The past decade has witnessed some dramatic developments in the field of theoretical physics, including advancements in supersymmetry and string theory. There have also been spectacular discoveries in astrophysics and cosmology. The next few years will be an exciting time in particle physics with the start of the Large Hadron Collider at CERN.

This book is a comprehensive introduction to these recent developments, and provides the tools necessary to develop models of phenomena important in both accelerators and cosmology. It contains a review of the Standard Model, covering non-perturbative topics, and a discussion of grand unified theories and magnetic monopoles. The book focuses on three principal areas: supersymmetry, string theory, and astrophysics and cosmology. The chapters on supersymmetry introduce the basics of supersymmetry and its phenomenology, and cover dynamics, dynamical supersymmetry breaking, and electric–magnetic duality. The book then introduces general relativity and the big bang theory, and the basic issues in inflationary cosmologies. The section on string theory discusses the spectra of known string theories, and the features of their interactions. The compactification of string theories is treated extensively. The book also includes brief introductions to technicolor, large extra dimensions, and the Randall–Sundrum theory of warped spaces.

*Supersymmetry and String Theory* will enable readers to develop models for new physics, and to consider their implications for accelerator experiments. This will be of great interest to graduates and researchers in the fields of particle theory, string theory, astrophysics, and cosmology. The book contains several problems and password-protected solutions will be available to lecturers at www.cambridge.org/9780521858410.

**Michael Dine** is Professor of Physics at the University of California, Santa Cruz. He is an A. P. Sloan Foundation Fellow, a Fellow of the American Physical Society, and a Guggenheim Fellow. Prior to this Professor Dine was a research associate at the Stanford Linear Accelerator Center, a long-term member of the institute for Advanced Study, and Henry Semat Professor at the City College of the City University of New York.
“An excellent and timely introduction to a wide range of topics concerning physics beyond the standard model, by one of the most dynamic researchers in the field. Dine has a gift for explaining difficult concepts in a transparent way. The book has wonderful insights to offer beginning graduate students and experienced researchers alike.”

Nima Arkani-Hamed, Harvard University

“How many times did you need to find the answer to a basic question about the formalism and especially the phenomenology of general relativity, the Standard Model, its supersymmetric and grand unified extensions, and other serious models of new physics, as well as the most important experimental constraints and the realization of the key models within string theory? Dine’s book will solve most of these problems for you and give you much more, namely the state-of-the-art picture of reality as seen by a leading superstring phenomenologist.”

Lubos Motl, Harvard University

“This book gives a broad overview of most of the current issues in theoretical high energy physics. It introduces and discusses a wide range of topics from a pragmatic point of view. Although some of these topics are addressed in other books, this one gives a uniform and self-contained exposition of all of them. The book can be used as an excellent text in various advanced graduate courses. It is also an extremely useful reference book for researchers in the field, both for graduate students and established senior faculty. Dine’s deep insights and broad perspective make this book an essential text. I am sure it will become a classic. Many physicists expect that with the advent of the LHC a revival of model building will take place. This book is the best tool kit a modern model builder will need.”

Nathan Seiberg, Institute for Advanced Study, Princeton
This book is dedicated to Mark and Esther Dine

**Part 1  Effective field theory: the Standard Model, supersymmetry, unification**

1 Before the Standard Model  
Suggested reading

2 The Standard Model  
2.1 Yang–Mills theory  
2.2 Realizations of symmetry in quantum field theory  
2.3 The quantization of Yang–Mills theories  
2.4 The particles and fields of the Standard Model  
2.5 The gauge boson masses  
2.6 Quark and lepton masses  
Suggested reading  
Exercises

3 Phenomenology of the Standard Model  
3.1 The weak interactions  
3.2 The quark and lepton mass matrices  
3.3 The strong interactions  
3.4 The renormalization group  
3.5 Calculating the beta function  
3.6 The strong interactions and dimensional transmutation  
3.7 Confinement and lattice gauge theory  
3.8 Strong interaction processes at high momentum transfer  
Suggested reading  
Exercises

4 The Standard Model as an effective field theory 63
  4.1 Lepton and baryon number violation 66
  4.2 Challenges for the Standard Model 70
  4.3 The hierarchy problem 71
  4.4 Dark matter and dark energy 72
  4.5 Summary: successes and limitations of the Standard Model 73
      Suggested reading 73

5 Anomalies, instantons and the strong CP problem 75
  5.1 The chiral anomaly 76
  5.2 A two-dimensional detour 81
  5.3 Real QCD 89
  5.4 The strong CP problem 100
  5.5 Possible solutions of the strong CP problem 102
      Suggested reading 105
      Exercises 106

6 Grand unification 107
  6.1 Cancellation of anomalies 110
  6.2 Renormalization of couplings 110
  6.3 Breaking to $SU(3) \times SU(2) \times U(1)$ 111
  6.4 $SU(2) \times U(1)$ breaking 112
  6.5 Charge quantization and magnetic monopoles 113
  6.6 Proton decay 114
  6.7 Other groups 114
      Suggested reading 117
      Exercises 117

7 Magnetic monopoles and solitons 119
  7.1 Solitons in $1 + 1$ dimensions 120
  7.2 Solitons in $2 + 1$ dimensions: strings or vortices 122
  7.3 Magnetic monopoles 122
  7.4 The BPS limit 124
  7.5 Collective coordinates for the monopole solution 125
  7.6 The Witten effect: the electric charge in the presence of $\theta$ 127
  7.7 Electric–magnetic duality 128

As this is being written, particle physics stands on the threshold of a new era, with the commissioning of the Large Hadron Collider (LHC) not even two years away. In writing this book, I hope to help prepare graduate students and postdoctoral researchers for what will hopefully be a period rich in new data and surprising phenomena.

The Standard Model has reigned triumphant for three decades. For just as long, theorists and experimentalists have speculated about what might lie beyond. Many of these speculations point to a particular energy scale, the teraelectronvolt (TeV) scale which will be probed for the first time at the LHC. The stimulus for these studies arises from the most mysterious – and still missing – piece of the Standard Model: the Higgs boson. Precision electroweak measurements strongly suggest that this particle is elementary (in that any structure is likely far smaller than its Compton wavelength), and that it should be in a mass range where it will be discovered at the LHC. But the existence of fundamental scalars is puzzling in quantum field theory, and strongly suggests new physics at the TeV scale. Among the most prominent proposals for this physics is a hypothetical new symmetry of nature, supersymmetry, which is the focus of much of this text. Others, such as technicolor, and large or warped extra dimensions, are also treated here.

Even as they await evidence for such new phenomena, physicists have become more ambitious, attacking fundamental problems of quantum gravity, and speculating on possible final formulations of the laws of nature. This ambition has been fueled by string theory, which seems to provide a complete framework for the quantum mechanics of gauge theory and gravity. Such a structure is necessary to give a framework to many speculations about beyond the Standard Model physics. Most models of supersymmetry breaking, theories of large extra dimensions, and warped spaces cannot be discussed in a consistent way otherwise.

It seems, then, quite likely that a twenty-first-century particle physicist will require a working knowledge of supersymmetry and string theory, and in writing this
text I hope to provide this. The first part of the text is a review of the Standard Model. It is meant to complement existing books, providing an introduction to perturbative and phenomenological aspects of the theory, but with a lengthy introduction to non-perturbative issues, especially in the strong interactions. The goal is to provide an understanding of chiral symmetry breaking, anomalies and instantons, suitable for thinking about possible strong dynamics, and about dynamical issues in supersymmetric theories. The first part also introduces grand unification and magnetic monopoles.

The second part of the book focuses on supersymmetry. In addition to global supersymmetry in superspace, there is a study of the supersymmetry currents, which are important for understanding dynamics, and also for understanding the BPS conditions which play an important role in field theory and string theory dualities. The MSSM is developed in detail, as well as the basics of supergravity and supersymmetry breaking. Several chapters deal with supersymmetry dynamics, including dynamical supersymmetry breaking, Seiberg dualities and Seiberg–Witten theory. The goal is to introduce phenomenological issues (such as dynamical supersymmetry breaking in hidden sectors and its possible consequences), and also to illustrate the control that supersymmetry provides over dynamics.

I then turn to another critical element of beyond the Standard Model physics: general relativity, cosmology and astrophysics. The chapter on general relativity is meant as a brief primer. The approach is more field theoretic than geometrical, and the uninitiated reader will learn the basics of curvature, the Einstein Lagrangian, the stress tensor and equations of motion, and will encounter the Schwarzschild solution and its features. The subsequent two chapters introduce the basic features of the FRW cosmology, and then very early universe cosmology: cosmic history, inflation, structure formation, dark matter and dark energy. Supersymmetric dark matter and axion dark matter, and mechanisms for baryogenesis, are all considered.

The third part of the book is an introduction to string theory. My hope, here, is to be reasonably comprehensive while not being excessively technical. These chapters introduce the various string theories, and quickly compute their spectra and basic features of their interactions. Heavy use is made of light cone methods. The full machinery of conformal and superconformal ghosts is described but not developed in detail, but conformal field theory techniques are used in the discussion of string interactions. Heavy use is also made of effective field theory techniques, both at weak and strong coupling. Here, the experience in the first half of the text with supersymmetry is invaluable; again supersymmetry provides a powerful tool to constrain and understand the underlying dynamics. Two lengthy chapters deal with string compactifications; one is devoted to toroidal and orbifold compactifications, which are described by essentially free strings; the other introduces the basics of Calabi–Yau compactification. Four appendices make up the final part of this book.
The emphasis in all of this discussion is on providing tools with which to consider how string theory might be related to observed phenomena. The obstacles are made clear, but promising directions are introduced and explored. I also attempt to stress how string theory can be used as a testing ground for theoretical speculations. I have not attempted a complete bibliography. The suggested reading in each chapter directs the reader to a sample of reviews and texts.

What I know in field theory and string theory is the result of many wonderful colleagues. It is impossible to name all of them, but Tom Appelquist, Nima Arkani-Hamed, Tom Banks, Savas Dimopoulos, Willy Fischler, Michael Green, David Gross, Howard Haber, Jeff Harvey, Shamit Kachru, Andre Linde, Lubos Motl, Ann Nelson, Yossi Nir, Michael Peskin, Joe Polchinski, Pierre Ramond, Lisa Randall, John Schwarz, Nathan Seiberg, Eva Silverstein, Bunji Sakita, Steve Shenker, Leonard Susskind, Scott Thomas, Steven Weinberg, Frank Wilczek, Mark Wise and Edward Witten have all profoundly influenced me, and this influence is reflected in this text. Several of them offered comments on the text or provided specific advice and explanations, for which I am grateful. I particularly wish to thank Lubos Motl for reading the entire manuscript and correcting numerous errors. Needless to say, none of them are responsible for the errors which have inevitably crept into this book.

Some of the material, especially on anomalies and aspects of supersymmetry phenomenology, has been adapted from lectures given at the Theoretical Advanced Study Institute, held in Boulder, Colorado. I am grateful to K. T. Manahathapa for his help during these schools, and to World Scientific for allowing me to publish these excerpts. The lectures “Supersymmetry Phenomenology with a Broad Brush” appeared in *Fields, Strings and Duality*, ed. C. Efthimiou and B. Greene (Singapore: World Scientific, 1997); “TASI Lectures on M Theory Phenomenology” appeared in *Strings, Branes and Duality*, ed. C. Efthimiou and B. Greene (Singapore: World Scientific, 2001); and “The Strong CP Problem” in *Flavor Physics for the Millennium: TASI 2000*, ed. J. L. Rosner (Singapore: World Scientific, 2000).

I have used much of the material in this book as the basis for courses, and I am also grateful to students and postdocs (especially Patrick Fox, Assaf Shomer, Sean Echols, Jeff Jones, John Mason, Alex Morisse, Deva O’Neil, and Zheng Sun) at Santa Cruz who have patiently suffered through much of this material as it was developed. They have made important comments on the text and in the lectures, often filling in missing details. As teachers, few of us have the luxury of devoting a full year to topics such as this. My intention is that the separate supersymmetry or string parts are suitable for a one-quarter or one-semester special topics course.

Finally, I wish to thank Aviva, Jeremy, Shifrah, and Melanie for their love and support.
A note on choice of metric

There are two popular choices for the metric of flat Minkowski space. One, often referred to as the “West Coast Metric,” is particularly convenient for particle physics applications. Here,

$$ds^2 = dt^2 - d\vec{x}^2 = \eta_{\mu\nu} dx^\mu dx^\nu$$  \hspace{1cm} (0.1)

This has the virtue that $p^2 = E^2 - \vec{p}^2 = m^2$. It is the metric of many standard texts in quantum field theory. But it has the annoying feature that ordinary, space-like intervals – conventional lengths – are treated with a minus sign. So in most general relativity textbooks, as well as string theory textbooks, the “East Coast Metric” is standard:

$$ds^2 = -dt^2 + d\vec{x}^2.$$  \hspace{1cm} (0.2)

Many physicists, especially theorists, become so wedded to one form or another that they resist – or even have difficulty – switching back and forth. This is a text, however, meant to deal both with particle physics and with general relativity and string theory. So, in the first half of the book, which deals mostly with particle physics and quantum field theory, we will use the “West Coast” convention. In the second half, dealing principally with general relativity and string theory, we will switch to the “East Coast” convention. For both the author and the readers, this may be somewhat disconcerting. While I have endeavored to avoid errors from this somewhat schizophrenic approach, some have surely slipped by. But I believe that this freedom to move back and forth between the two conventions will be both convenient and healthy. If nothing else, this is probably the first textbook in physics in which the author has deliberately used both conventions (many have done so inadvertently).

At a serious level, the researcher must always be careful in computations to be consistent. It is particularly important to be careful in borrowing formulas from
papers and texts, and especially in downloading computer programs, to make sure one has adequate checks on such matters of signs. I will appreciate being informed of any such inconsistencies, as well as of other errors, both serious and minor, which have crept into this text.
Even as this book was going to press, there were important developments in a number of these subjects. The website http://scipp.ucsc.edu/~dine/book/book.html will contain

(1) updates,
(2) errata,
(3) solutions of selected problems, and
(4) additional selected reading.
Part 1

Effective field theory: the Standard Model, supersymmetry, unification
Before the Standard Model

Two of the most profound scientific discoveries of the early twentieth century were special relativity and quantum mechanics. With special (and general) relativity came the notion that physics should be local. Interactions should be carried by dynamical fields in space-time. Quantum mechanics altered the questions which physicists asked about phenomena; the rules governing microscopic (and some macroscopic) phenomena were not those of classical mechanics. When these ideas are combined, they take on their full force, in the form of quantum field theory. Particles themselves are localized, finite-energy excitations of fields. Otherwise mysterious phenomena such as the connection of spin and statistics are immediate consequences of this marriage. But quantum field theory does pose a serious challenge. The Schrödinger equation seems to single out time, making a manifestly relativistic description difficult. More serious, but closely related, the number of degrees of freedom is infinite.

In the 1920s and 1930s, physicists performed conventional perturbation theory calculations in the quantum theory of electrodynamics, quantum electrodynamics or QED, and obtained expressions which were neither Lorentz invariant nor finite. Until the late 1940s, these problems stymied any quantitative progress, and there was serious doubt whether quantum field theory was a sensible framework for physics.

Despite these concerns, quantum field theory proved a valuable tool with which to consider problems of fundamental interactions. Yukawa proposed a field theory of the nuclear force, in which the basic quanta were mesons. The corresponding particle was discovered shortly after the Second World War. Fermi was aware of Yukawa’s theory, and proposed that the weak interactions arose through the exchange of some massive particle – essentially the $W^\pm$ bosons which were finally discovered in the 1980s. The large mass of the particle accounted for both the short range and the strength of the weak force. Because of the very short range of the force, one could describe it in terms of four fields interacting at a point. In the early days of the theory, these were the proton, neutron, electron and neutrino.
Viewed as a theory of four-fermion interactions, Fermi’s theory was very successful, accounting for all experimental weak interaction results until well into the 1970s. Yet the theory raised even more severe conceptual problems than QED. At high energies, the amplitudes computed in the leading approximation violated unitarity, and higher-order terms in perturbation theory were very divergent.

The difficulties of QED were overcome in the late 1940s, by Bethe, Dyson, Feynman, Schwinger, Tomanaga and others, as experiments in atomic physics demanded high-precision QED calculations. As a result of their work, it was now possible to perform perturbative QED calculations in a manifestly Lorentz invariant fashion. Exploiting the covariance, the infinities could be controlled and, over time, their significance came to be understood. Quantum electrodynamics achieved extraordinary successes, explaining the magnetic moment of the electron to extraordinary precision, as well as the Lamb shift in hydrogen and other phenomena. One now, for the first time, had an example of a system of physical law, consistent both with Einstein’s principles of relativity and with quantum mechanics.

There were, however, many obstacles to extending this understanding to the strong and weak interactions, and at times it seemed that some other framework might be required. The difficulties came in various types. The infinities of Fermi’s theory could not be controlled as in electrodynamics. Even postulating the existence of massive particles to mediate the force did not solve the problems. But the most severe difficulties came in the case of the strong interactions. The 1950s and 1960s witnessed the discovery of hundreds of hadronic resonances. It was hard to imagine that each of these should be described by still another fundamental field. Some theorists pronounced field theory dead, and sought alternative formulations (among the outgrowths of these explorations was string theory, which has emerged as the most promising setting for a quantum theory of gravitation). Gell-Mann and Zweig realized that quarks could serve as an organizing principle. Originally, there were only three, $u$, $d$, and $s$, with baryon number $1/3$ and charges $2/3$, $-1/3$ and $-1/3$ respectively. All of the known hadrons could be understood as bound states of objects with these quantum numbers. Still, there remained difficulties. First, the quarks were strongly interacting, and there were no successful ideas for treating strongly interacting fields. Second, searches for quarks came up empty handed.

In the late 1960s, a dramatic series of experiments at SLAC, and a set of theoretical ideas due to Feynman and Bjorken, changed the situation again. Feynman had argued that one should take seriously the idea of quarks as dynamical entities (for a variety of reasons, he hesitated to call them quarks, referring to them as “partons”). He conjectured that these partons would behave as nearly free particles in situations where momentum transfers were large. He and Bjorken realized that this picture implied scaling in deep inelastic scattering phenomena. The experiments at SLAC
exhibited just this phenomenon and showed that the partons carried the electric charges of the $u$ and $d$ quarks.

But this situation was still puzzling. Known field theories did not behave in the fashion conjectured by Feynman and Bjorken. The interactions of particles typically became stronger as the energies and momentum transfers grew. This is the case, for example, in quantum electrodynamics, and a simple quantum mechanical argument, based on unitarity and relativity, would seem to suggest it is general. But there turned out to be an important class of theories with the opposite property.

In 1954, Yang and Mills wrote down a generalization of electrodynamics, where the $U(1)$ symmetry group is enlarged to a non-Abelian group. While mathematically quite beautiful, these non-Abelian gauge theories remained oddities for some time. First, their possible place in the scheme of things was not known (Yang and Mills themselves suggested that perhaps their vector particles were the $\rho$ mesons). Moreover, their quantization was significantly more challenging than that of electrodynamics. It was not at all clear that these theories really made sense at the quantum level, respecting both the principles of Lorentz invariance and unitarity. The first serious effort to quantize Yang–Mills theories was probably due to Schwinger, who chose a non-covariant but manifestly unitary gauge, and carefully verified that the Poincaré algebra is satisfied. The non-covariant gauge, however, was exceptionally awkward. Real progress in formulating a covariant perturbation expansion was due to Feynman, who noted that naive Feynman rules for these theories were not unitary, but that this could be fixed, at least in low orders, by adding a set of fictitious fields (“ghosts”). A general formulation was provided by Faddeev and Popov, who derived Feynman’s covariant rules in a path integral formulation, and showed their formal equivalence to Schwinger’s manifestly unitary formulation. A convincing demonstration that these theories were unitary, covariant and renormalizable was finally given in the early 1970s by ’t Hooft and Veltman, who developed elegant and powerful techniques for doing real calculations as well as formal proofs.

In the original Yang–Mills theories, the vector bosons were massless and their possible connections to known phenomena obscure. However, Peter Higgs discovered a mechanism by which these particles could become massive. In 1967, Weinberg and Salam wrote down a Yang–Mills theory of the weak interactions based on the Higgs mechanism. This finally realized Fermi’s idea that the weak interactions arise from the exchange of a very massive particle. To a large degree this work was ignored, until ’t Hooft and Veltman proved the unitarity and renormalizability of these theories. At this point the race to find precisely the correct theory and study its experimental consequences was on; Weinberg and Salam’s first guess turned out to be correct.

The possible role of Yang–Mills fields in strong interactions was, at first sight, even more obscure. To complete the story required another important fact of
Before the Standard Model

hadronic physics. While the quark model was very successful, it was also puzzling. The quarks were spin $1/2$ particles, yet models of the hadrons seemed to require that the hadronic wave functions were symmetric under interchange of quark quantum numbers. A possible resolution, suggested by Greenberg, was that the quarks carried an additional quantum number, called color, coming in three possible types. The statistics puzzle was solved if the hadron wave functions were totally antisymmetric in color. This hypothesis required that the color symmetry, unlike, say, isospin, would be exact, and thus special. While seemingly contrived, it explained two other facts: the width of the $\pi^0$ meson (which was otherwise too small by a factor of three) and the value of the $e^+e^-$ cross section to hadrons.

To a number of researchers, the exactness of this symmetry suggested a possible role for Yang–Mills theory. So, in retrospect, there was the obvious question: could it be that an $SU(3)$ Yang–Mills theory, describing the interactions of quarks, would exhibit the property required to explain Bjorken scaling: the interactions become weak at short distances? Of course, things were not quite so obvious at the time. The requisite calculation had already been done by ’t Hooft, but the result seems not to have been widely known or its significance appreciated. David Gross and his student Frank Wilczek set out to prove that no field theory had the required scaling property, while Sidney Coleman, apparently without any particular prejudice, assigned the problem to his graduate student, David Politzer. All soon realized that Yang–Mills theories do have the property of asymptotic freedom: the interactions become weak at high-momentum transfers or at short distances.

Experiment and theory now entered a period of remarkable convergence. Alternatives to the Weinberg–Salam theory were quickly ruled out. The predictions of QCD were difficult, at first, to verify in detail. The theory predicted small violations of Bjorken scaling, depending logarithmically on energy, and it took many years to convincing measure them. But there was another critical experimental development which clinched the picture. The existence of a heavy quark beyond the $u$, $d$ and $s$, had been predicted by Glashow, Iliopoulos and Maiani, and was a crucial part of the developing Standard Model. The mass of this charm quark had been estimated by Gaillard and Lee. Appelquist and Politzer predicted, almost immediately after the discovery of asymptotic freedom, that heavy quarks would be bound in narrow vector resonances. In 1974 a narrow resonance was discovered in $e^+e^-$ annihilation, the $J/\psi$ particle, which was quickly identified as a bound state of a charmed quark and its antiparticle.

Over the next 25 years, this Standard Model was subjected to more and more refined tests. One feature absent from the original Standard Model was CP (T) violation. Kobiyashi and Maskawa pointed out that, if there were a third generation of quarks and leptons, the theory could accommodate the observed CP violation in the $K$ meson system. Two more quarks and a lepton were discovered, and their
interactions and behavior were as expected within the Standard Model. Jets of particles which could be associated with gluons were seen in the late 1970s. The $W$ and $Z$ particles were produced in accelerators in the early 1980s. At CERN and SLAC, precision measurements of the $Z$ mass and width provided stringent tests of the weak-interaction part of the theory. Detailed measurements in deep inelastic scattering and in jets provided precise confirmation of the logarithmic scaling violations predicted by QCD. The Standard Model passed every test.

So why write a book about physics beyond the Standard Model? For all of its simplicity and success in reproducing the interactions of elementary particles, the Standard Model cannot represent a complete description of nature. In the first few chapters of this book, we will review the Standard Model and its successes, and then we will discuss some of the theory’s limitations. These include the hierarchy problem, which, at its most primitive level, represents a failure of dimensional analysis; the presence of a large number of parameters; the incompatibility of quantum mechanics with Einstein’s theory of general relativity; the inability of the theory to account for the small, non-zero value of the cosmological constant (an even more colossal failure of dimensional analysis), and the failure of the theory to account for basic features of our universe: the excess of baryons over anti-baryons, the dark matter, and structure. Then we will set out on an exploration of possible phenomena which might address these questions. These include supersymmetry, technicolor and large or warped extra dimensions, as possible solutions to the hierarchy problem; grand unification, as a partial solution to the overabundance of parameters, and superstring theory, as a possible solution to the problem of quantizing gravity, which incorporates many features of these other proposals.

Suggested reading

A complete bibliography of the Standard Model would require a book by itself. A good deal of the history of special relativity, quantum mechanics and quantum field theory can be found in Inward Bound, by Abraham Pais (1986), which also includes an extensive bibliography. The development of the Standard Model is also documented in this very readable book. As a minor historical note, I would add that the earliest reference where I have heard the observation that a Yang–Mills theory might underly the strong interactions is due to Feynman, c. 1963 (Roger Dashen, personal communication, 1981), who pointed out that, in an $SU(3)$ Yang–Mills theory, three quarks would be bound together, as well as quark–antiquark pairs.
The Standard Model

The interactions of the Standard Model give rise to the phenomena of our day to day experience. They explain virtually all of the particles and interactions which have been observed in accelerators. Yet the underlying laws can be summarized in a few lines. In this chapter, we describe the ingredients of this theory and some of its important features. Many dynamical questions will be studied in subsequent chapters. For detailed comparison of theory and experiment, there are a number of excellent texts, described in the suggested reading at the end of the chapter.

2.1 Yang–Mills theory

By the early 1950s, physicists were familiar with approximate global symmetries like isospin. Yang and Mills argued that the lesson of Einstein’s general theory was that symmetries, if fundamental, should be local. In ordinary electrodynamics, the gauge symmetry is a local, Abelian symmetry. Yang and Mills explained how to generalize this to a non-Abelian symmetry group. Let’s first review the case of electrodynamics. The electron field, $\psi(x)$, transforms under a gauge transformation as:

$$\psi(x) \rightarrow e^{i\alpha(x)}\psi(x) = g_{\alpha}(x)\psi(x).$$ (2.1)

We can think of $g_\alpha(x) = e^{i\alpha(x)}$ as a group element in the group $U(1)$. The group is Abelian, $g_\alpha g_\beta = g_\beta g_\alpha = g_{\alpha+\beta}$. Quantities like $\bar{\psi}\psi$ are gauge invariant, but derivative terms, like $i\bar{\psi}\not{\partial}\psi$, are not. In order to write derivative terms in an action or equations of motion, one needs to introduce a gauge field, $A_\mu$, transforming under the symmetry transformation as:

$$A_\mu \rightarrow A_\mu + \partial_\mu \alpha$$
$$= A_\mu + ig(x)\partial_\mu g^\dagger(x).$$ (2.2)
This second form allows generalization more immediately to the non-Abelian case. Given $A_\mu$ and its transformation properties, we can define a covariant derivative:

$$D_\mu \psi = (\partial_\mu - iA_\mu)\psi.$$

This derivative has the property that it transforms like $\psi$ itself under the symmetry:

$$D_\mu \psi \to g(x)D_\mu \psi.$$

We can also form a gauge-invariant object out of the gauge fields, $A_\mu$, themselves. A simple way to do this is to construct the commutator of two covariant derivatives:

$$F_{\mu\nu} = i[D_\mu, D_\nu] = \partial_\mu A_\nu - \partial_\nu A_\mu.$$

This form of the gauge transformations may be somewhat unfamiliar. Note, in particular, that the charge of the electron, $e$ (the gauge coupling) does not appear in the transformation laws. Instead, the gauge coupling appears when we write a gauge-invariant Lagrangian:

$$L = i\bar{\psi}D\psi - m\bar{\psi}\psi - \frac{1}{4e^2}F_{\mu\nu}^2.$$

The more familiar formulation is obtained if we make the replacement:

$$A_\mu \to eA_\mu.$$

In terms of this new field, the gauge transformation law is:

$$A_\mu \to A_\mu + \frac{1}{e}\partial_\mu \alpha,$$

and the covariant derivative is:

$$D_\mu \psi = (\partial_\mu - ieA_\mu)\psi.$$

We can generalize this to a non-Abelian group, $G$, by taking $\psi$ to be a field (fermion or boson) in some representation of the group. $g(x)$ is then a matrix which describes a group transformation acting in this representation. Formally, the transformation law is the same as before:

$$\psi \to g(x)\psi(x),$$

but the group composition law is more complicated,

$$g_\alpha g_\beta \neq g_\beta g_\alpha.$$

The gauge field, $A_\mu$, is now a matrix-valued field, transforming in the adjoint representation of the gauge group:

$$A_\mu \to gA_\mu g^\dagger + ig(x)\partial_\mu g^\dagger(x).$$
2.1 Yang–Mills theory

The covariant derivative also, formally, looks exactly as before:

\[
D_\mu \psi = (\partial_\mu - i A_\mu)\psi; \quad D_\mu \psi \rightarrow g(x)D_\mu \psi.
\] (2.13)

Like \( A_\mu \), the field strength is a matrix-valued field:

\[
F_{\mu \nu} = i[D_\mu, D_\nu] = \partial_\mu A_\nu - \partial_\nu A_\mu - i[A_\mu, A_\nu].
\] (2.14)

Note that \( F_{\mu \nu} \) is not gauge invariant, but rather covariant:

\[
F_{\mu \nu} \rightarrow g F_{\mu \nu} g^\dagger,
\] (2.15)

i.e. it transforms like a field in the adjoint representation, with no inhomogeneous term.

The gauge-invariant action is formally almost identical to that of the \( U(1) \) theory:

\[
L = i \bar{\psi} D\psi - m \bar{\psi}\psi - \frac{1}{2g^2} \text{Tr} F_{\mu \nu}^2.
\] (2.16)

Here we have changed the letter we use to denote the coupling constant; we will usually reserve \( e \) for the electron charge, using \( g \) for a generic gauge coupling. Note also that it is necessary to take a trace of \( F^2 \) to obtain a gauge-invariant expression.

The matrix form for the fields may be unfamiliar, but it is very powerful. One can recover expressions in terms of more conventional fields by defining

\[
A_\mu = A_\mu^a T_a,
\] (2.17)

where \( T_a \) are the group generators in representation appropriate to \( \psi \). Then for \( SU(N) \), for example, if the \( T_a \)s are in the fundamental representation,

\[
\text{Tr}(T_a T_b) = \frac{1}{2} \delta_{ab}; \quad [T^a, T^b] = i f^{abc} T^c,
\] (2.18)

where \( f^{abc} \) are the structure constants of the group, and

\[
A_\mu^a = 2 \text{Tr}(T_a A_\mu); \quad F_{\mu \nu}^a = \partial_\mu A_\nu^a - \partial_\nu A_\mu^a + f_{abc} A_\mu^a A_\nu^b.
\] (2.19)

While formally almost identical, there are great differences between the Abelian and non-Abelian theories. Perhaps the most striking is that the equations for the \( A_\mu \)s are non-linear in non-Abelian theories. This behavior means that, unlike the case of Abelian gauge fields, a theory of non-Abelian fields without matter is a non-trivial, interacting theory with interesting properties. With and without matter fields, this will lead to much richer behavior even classically. For example, we will see that non-Abelian theories sometimes contain solitons, localized finite-energy solutions of the classical equations. The most interesting of these are magnetic monopoles. At the quantum level, these non-linearities lead to properties such as asymptotic freedom and confinement.
As we have written the action, the matter fields $\psi$ can appear in any representation of the group; one just needs to choose the appropriate matrices $T^a$. We can also consider scalars, as well as fermions. For a scalar field, $\phi$, we define the covariant derivative, $D_\mu \phi$ as before, and add to the action a term $|D_\mu \phi|^2$ for a complex field, or $(1/2)(D_\mu \phi)^2$ for a real field.

2.2 Realizations of symmetry in quantum field theory

The most primitive exercise we can do with the Yang–Mills Lagrangian is set $g = 0$ and examine the equations of motion for the fields $A_\mu$. If we choose the gauge $\partial_\mu A_\mu^a = 0$, all of the gauge fields obey

$$\partial^2 A_\mu^a = 0.$$ (2.20)

So, like the photon, all of the gauge fields, $A_\mu^a$, of the Yang–Mills theory are massless. At first sight, there is no obvious place for these fields in either the strong or the weak interactions. But it turns out that in non-Abelian theories, the possible ways in which the symmetry may be realized are quite rich. The symmetry can be realized in terms of massless gauge bosons; this is known as the Coulomb phase. This possibility is not relevant to the Standard Model, but will appear in some of our more theoretical considerations later. A second is known as the Higgs phase. In this phase, the gauge bosons are massive. In the third, the confinement phase, there are no physical states with the quantum numbers of isolated quarks (particles in the fundamental representation), and the gauge bosons are also massive. The second phase is relevant to the weak interactions; the third, confinement phase, to the strong interactions.\(^1\)

2.2.1 The Goldstone phenomenon

Before introducing the Higgs phase, it is useful to discuss global symmetries. While we will frequently argue, like Yang and Mills, that global symmetries are less fundamental than local ones, they are important in nature. Examples are isospin, the chiral symmetries of the strong interactions, and baryon number. We can represent the action of such a symmetry much as we represented the symmetry action in Yang–Mills theory:

$$\Phi \rightarrow g_\alpha \Phi$$ (2.21)

\(^1\) The differences between the confinement and Higgs phases are subtle, as first stressed by Fradkin, Shenker and ’t Hooft. But we now know that the Standard Model is well described by a weakly coupled field theory in the Higgs phase.
where $\Phi$ is some set of fields and $g$ is now a constant matrix, independent of space. Such symmetries are typically accidents of the low-energy theory. Isospin, for example, arises as we will see because the masses of the $u$ and $d$ quarks are small compared with other hadronic scales of quantum chromodynamics. Then $g$ is the matrix:

$$g\vec{\alpha} = e^{i\vec{\alpha}\cdot\vec{\sigma}/2} \quad (2.22)$$

acting on the $u$ and $d$ quark doublet. Note that $\vec{\alpha}$ is not a function of space, but it is a continuous parameter, so we will refer to such symmetries as continuous global symmetries. In the case of isospin, it is also important that the electromagnetic and weak interactions, which violate this symmetry, are small perturbations on the strong interactions.

The simplest model of a continuous global symmetry is provided by a complex field transforming under a $U(1)$ symmetry:

$$\phi \rightarrow e^{i\alpha}\phi. \quad (2.23)$$

We can take for the Lagrangian for this system:

$$\mathcal{L} = |\partial_\mu \phi|^2 - m^2|\phi|^2 - \frac{1}{2}\lambda|\phi|^4. \quad (2.24)$$

If $m^2 > 0$, and $\lambda$ is small, this is just a theory of a weakly interacting, complex scalar. The states of the theory can be organized as states of definite $U(1)$ charge. This is the unbroken phase. On the other hand, $m^2$ is just a parameter, and we can ask what happens if $m^2 = -\mu^2 < 0$. In this case, the potential,

$$V(\phi) = -\mu^2|\phi|^2 + \lambda|\phi|^4, \quad (2.25)$$

looks as in Fig. 2.1. There is a set of degenerate minima,

$$\langle \phi \rangle_\alpha = \frac{\mu}{\sqrt{2\lambda}} e^{i\alpha}. \quad (2.26)$$
These classical ground states are obtained from one another by symmetry transformations. Classically the theory has a set of degenerate ground states, labeled by $\alpha$; in somewhat more mathematical language, there is a manifold of vacuum states. Quantum mechanically, it is necessary to choose a particular value of $\alpha$. As explained in the next section, if one chooses $\alpha$, no local operator, e.g. no small perturbation, will take the system into another state of different $\alpha$. To simplify the writing, take $\alpha = 0$. Then we can parameterize:

$$\phi = \frac{1}{\sqrt{2}}(v + \sigma(x))e^{i\pi(x)/v} \approx \frac{1}{\sqrt{2}}(v + \sigma(x) + i\pi(x)).$$ (2.27)

Here $v = \mu/\sqrt{\lambda}$ is known as the “vacuum expectation value” of $\phi$. In terms of $\sigma$ and $\pi$, the Lagrangian takes the form:

$$L = \frac{1}{2}[(\partial_\mu \sigma)^2 + (\partial_\mu \pi)^2 - 2\mu^2\sigma^2 + O(\sigma, \pi)^3].$$ (2.28)

So we see that $\sigma$ is an ordinary, real scalar field of mass-squared $2\mu^2$, while the $\pi$ field is massless. The fact that the $\pi$ is massless is not a surprise: the mass represents the energy cost of turning on a zero-momentum excitation of $\pi$, but such an excitation is just a symmetry transformation of $\phi$, $v \to ve^{i\pi(0)}$. So there is no energy cost.

The appearance of massless particles when a symmetry is broken is known as the Nambu–Goldstone phenomenon, and $\pi$ is called a Nambu–Goldstone boson. In any theory with scalars, a choice of minimum may break some symmetry. This means that there is a manifold of vacuum states. The broken symmetry generators are those which transform the system from one point on this manifold to another. Because there is no energy cost associated with such a transformation, there is a massless particle associated with each broken symmetry generator. This result is very general. Symmetries can be broken not only by expectation values of scalar fields, but by expectation values of composite operators, and the theorem holds. A proof of this result is provided in Appendix B. In nature, there are a number of excitations which can be identified as Goldstone or almost Goldstone (“pseudo-Goldstone”) bosons. These include spin waves in solids and the pi mesons. We will have much more to say about the pions later.

### 2.2.2 Aside: choosing a vacuum

In quantum mechanics, there is no notion of a spontaneously broken symmetry. If one has a set of degenerate classical configurations, the ground state will invariably involve a superposition of these configurations. If we took $\sigma$ and $\pi$ to be functions only of $t$, then the $\sigma-\pi$ system would just be an ordinary quantum-mechanical
system with two degrees of freedom. Here $\sigma$ would correspond to an anharmonic oscillator of frequency $\omega = \sqrt{2}\mu$. Placing this particle in its ground state, one would be left with the coordinate $\pi$. Note that $\pi$, in Eq. (2.27), is an angle, like the azimuthal angle, $\phi$, in ordinary quantum mechanics. We could call its conjugate variable $L_z$. The lowest-lying state would be the zero-angular-momentum state, a uniform superposition of all values of $\pi$. In field theory at finite volume, the situation is similar. The zero-momentum mode of $\pi$ is again an angular variable, and the ground state is invariant under the symmetry. But at infinite volume, the situation is different. One is forced to choose a value of $\pi$.

This issue is most easily understood by considering a different problem: rotational invariance in a magnet. Consider Fig. 2.2, where we have sketched a ferromagnet with spins aligned at an angle $\theta$. We can ask: what is the overlap of two states, one with $\theta = 0$, one at $\theta$, i.e. what is $\langle \theta | 0 \rangle$? For a single site, the overlap between the state $|+\rangle$ and the rotated state is:

$$\langle + | e^{i_{\pi_1/2}} | + \rangle = \cos(\theta/2). \tag{2.29}$$

If there are $N$ such sites, the overlap behaves as

$$\langle \theta | 0 \rangle \sim (\cos(\theta/2))^N \tag{2.30}$$

i.e. it vanishes exponentially rapidly with the “volume,” $N$.

For a continuum field theory, states with differing values of the order parameter, $\nu$, also have no overlap in the infinite volume limit. This is illustrated by the theory of a scalar field with Lagrangian:

$$\mathcal{L} = \frac{1}{2}(\partial_\mu \phi)^2. \tag{2.31}$$
For this system, there is no potential, so the expectation value, \( \phi = v \), is not fixed. The Lagrangian has a symmetry, \( \phi \rightarrow \phi + \delta \), for which the charge is just

\[
Q = \int d^3 x \Pi(\vec{x})
\]  

(2.32)

where \( \Pi \) is the canonical momentum. So we want to study

\[
\langle v|0 \rangle = \langle 0|e^{iQ}|0 \rangle.
\]  

(2.33)

We must be careful how we take the infinite-volume limit. We will insist that this be done in a smooth fashion, so we will define:

\[
Q = \int d^3 x \partial_0 \phi e^{-\vec{x}^2/V^{2/3}} &= -i \int \frac{d^3 k}{(2\pi)^3} \sqrt{\omega_k} \left( \frac{V^{1/3}}{\sqrt{\pi}} \right)^3 e^{-\vec{k}^2 V^{2/3}/4} [a(\vec{k}) - a^\dagger(\vec{k})].
\]  

(2.34)

Now, one can evaluate the matrix element, using

\[
e^{A+B} = e^A e^B e^{(1/2)[A,B]} \]

(provided that the commutator is a c-number), giving

\[
\langle 0|e^{iQ}|0 \rangle = e^{-cv^2 V^{2/3}},
\]  

(2.35)

where \( c \) is a numerical constant. So the overlap vanishes with the volume. You can convince yourself that the same holds for matrix elements of local operators. This result does not hold in \( 0+1 \) and \( 1+1 \) dimensions, because of the severe infrared behavior of theories in low dimensions. This is known to particle physicists as Coleman’s theorem, and to condensed matter theorists as the Mermin–Wagner theorem. This theorem will make an intriguing appearance in string theory, where it is the origin of energy–momentum conservation.

### 2.2.3 The Higgs mechanism

Suppose that the \( U(1) \) symmetry of the previous section is local. In this case, even a spatially varying \( \pi(x) \) represents a symmetry transformation, and by a gauge choice it can be eliminated. In other words, by a gauge transformation, we can bring \( \phi \) to the form:

\[
\phi = \frac{1}{\sqrt{2}}(v + \sigma(x)).
\]  

(2.36)

In this gauge, the kinetic terms for \( \phi \) take the form:

\[
|D_\mu \phi|^2 = \frac{1}{2}(\partial_\mu \sigma)^2 + \frac{1}{2} A_\mu^2 v^2.
\]  

(2.37)
2.2 Realizations of symmetry in quantum field theory

The last term is a mass term for the gauge field. To determine the actual value of the mass, we need to examine the kinetic term for the gauge fields:

$$-\frac{1}{2g^2}(\partial_\mu A^\nu)^2 + \cdots.$$  \hfill (2.38)

So the gauge field has a mass $m_A^2 = g^2 v^2$.

This phenomenon, that the gauge boson becomes massive when the gauge symmetry is spontaneously broken, is known as the Higgs mechanism. While formally quite similar to the Goldstone phenomenon, it is also quite different. The fact that there is no massless particle associated with motion along the manifold of ground states is not surprising – these states are all physically equivalent. Symmetry breaking, in fact, is a puzzling notion in gauge theories, since gauge transformations describe entirely equivalent physics (gauge symmetry is often referred to as a redundancy in the description of a system). Perhaps the most important lesson here is that gauge invariance does not necessarily mean, as it does in electrodynamics, that the gauge bosons are massless.

### 2.2.4 Goldstone and Higgs phenomena for non-Abelian symmetries

Both the Goldstone and Higgs phenomena generalize to non-Abelian symmetries. In the case of global symmetries, for every generator of a broken global symmetry, there is a massless particle. For local symmetries, each broken generator gives rise to a massive gauge boson.

As an example, relevant both to the strong and the weak interactions, consider a theory with a symmetry $SU(2)_L \times SU(2)_R$. Take $M$ to be a Hermitian, matrix field,

$$M = \sigma + i \vec{\pi} \cdot \vec{\sigma}.$$  \hfill (2.39)

Under the symmetry, which we first take to be global, $M$ transforms as

$$M \rightarrow g_L M g_R$$  \hfill (2.40)

with $g_L$ and $g_R$ $SU(2)$ matrices. We can take the Lagrangian to be

$$\mathcal{L} = \text{Tr} (\partial_\mu M^\dagger \partial^\mu M) - V(M^\dagger M).$$  \hfill (2.41)

This Lagrangian respects the symmetry. If the curvature of the potential at the origin is negative, $M$ will acquire an expectation value. If we take:

$$\langle M \rangle = \langle \sigma \rangle$$  \hfill (2.42)

then some of the symmetry is broken. However, the expectation value of $M$ is invariant under the subgroup of the full symmetry group with $g_L = g_R$. In other words,
the unbroken symmetry is $SU(2)$. Under this symmetry, the fields $\vec{\pi}$ transform as a vector. In the case of the strong interactions, this unbroken symmetry can be identified with isospin. In the case of the weak interactions, there is an approximate global symmetry reflected in the masses of the $W$ and $Z$ particles, as we will discuss later.

2.2.5 Confinement

There is still another possible realization of gauge symmetry: confinement. This is crucial to our understanding of the strong interactions. As we will see, Yang–Mills theories, without too much matter, become weak at short distances. They become strong at large distances. This is just what is required to understand the qualitative features of the strong interactions: free quark and gluon behavior at very large momentum transfers, but strong forces at larger distances, so that there are no free quarks or gluons. As is the case in the Higgs mechanism, there are no massless particles in the spectrum of hadrons: QCD is said to have a “mass gap.” These features of strong interactions are supported by extensive numerical calculations, but they are hard to understand through simple analytic or qualitative arguments (indeed, if you can offer such an argument, you can win one of the Clay prizes of $1$ million). We will have more to say about the phenomenon of confinement when we discuss lattice gauge theories.

One might wonder: what is the difference between the Higgs mechanism and confinement? This question was first raised by Fradkin and Shenker and by ’t Hooft, who also gave an answer: there is often no qualitative difference. The qualitative features of a Higgs theory like the weak interactions can be reproduced by a confined, strongly interacting theory. However, the detailed predictions of the weakly interacting Weinberg–Salaam theory are in close agreement with experiment, and those of the strongly interacting theory are not.

2.3 The quantization of Yang–Mills theories

In this book, we will encounter a number of interesting classical phenomena in Yang–Mills theory but, in most of the situations in nature which concern us, we are interested in the quantum behavior of the weak and strong interactions. Abelian theories such as QED are already challenging. One can perform canonical quantization in a gauge, such as Coulomb gauge or a light cone gauge, in which unitarity is manifest—all of the states have positive norm. But in such a gauge, the covariance of the theory is hard to see. Or one can choose a gauge where Lorentz invariance is manifest, but not unitarity. In QED it is not too difficult to show at the level of Feynman diagrams that these gauge choices are equivalent. In non-Abelian theories, canonical quantization is still more challenging. Path integral methods provide a much more powerful approach to the quantization of these theories.
2.3 The quantization of Yang–Mills theories

A brief review of path integration appears in Appendix C. Here we discuss gauge fixing and derive the Feynman rules. We start with the gauge fields alone; adding the matter fields – scalars or fermions – is not difficult. The basic path integral is:

$$\int [dA_\mu] e^{iS}.$$  \hfill (2.43)

The problem is that this integral includes a huge redundancy: the gauge transformations. To deal with this, we want to make a gauge choice, for example:

$$G^a(A^a_\mu) = \partial_\mu A^{\mu a} = 0.$$  \hfill (2.44)

We can’t simply insert this in the path integral without altering its value. Instead, we insert 1 in the form:

$$1 = \int [dg] \delta(G(A^g_\mu)) \Delta[A].$$  \hfill (2.45)

Here we have reverted to our matrix notation: $G$ is a general gauge fixing condition; $A^g_\mu$ denotes the gauge transform of $A_\mu$ by $g$. The $\Delta$ is a functional determinant, known as the Faddeev–Popov determinant. Note that $\Delta$ is gauge invariant, $\Delta[A^h] = \Delta[A]$. This follows from the definition:

$$\int [dg]\delta(G(A^{hg}_\mu)) = \int [dg]\delta(G(A^g_\mu))$$  \hfill (2.46)

where, in the last step, we have made the change of variables $g \rightarrow h^{-1}g$. We can write a more explicit expression for $\Delta$ as a determinant. To do this, we first need an expression for the variation of the $A$ under an infinitesimal gauge transformation. Writing $g = 1 + i\omega$, and using the matrix form for the gauge field,

$$\delta A_\mu = \partial_\mu \omega + i[\omega, A_\mu].$$  \hfill (2.47)

This can be written elegantly as a covariant derivative of $\omega$, where $\omega$ is thought of as a field in the adjoint representation:

$$\delta A_\mu = D_\mu \omega.$$  \hfill (2.48)

If we make the specific choice $G = \partial_\mu A^\mu$, to evaluate $\Delta$ we need to expand $G$ about the field $A_\mu$ for which $G = 0$:

$$G(A + \delta A) = \partial_\mu D^\mu \omega = \partial^2 \omega + i[A_\mu, \partial_\mu \omega]$$  \hfill (2.49)

or, in the index form:

$$G(A^a_\mu) = (\partial^2 \delta^{ac} + f^{abc} A^{\mu b} \partial_\mu) \omega^c.$$  \hfill (2.50)

So

$$\Delta[A] = \det[\partial^2 \delta^{ac} + f^{abc} A^{\mu b} \partial_\mu]^{-1/2}.$$  \hfill (2.51)

We will discuss strategies to evaluate this determinant shortly.
At this stage, we have reduced the path integral to:

\[ Z = \int [dA_\mu] \delta(G(A)) \Delta[A] e^{iS} \]  

and we can write down Feynman rules. The \( \delta \)-function remains rather awkward to deal with, though, and this expression can be simplified through the following trick. Introduce a function, \( \omega \), and average over \( \omega \) with a Gaussian weight factor:

\[ Z = \int [d\omega] e^{i \int d^4x(\omega^2/\xi)} \sum \int [dA_\mu] \delta(G(A) - \omega) \Delta[A] e^{iS}. \]  

We can do the integral over the \( \delta \)-function. The quadratic terms in the exponent are now:

\[ \int d^4x A^{\mu a} \left[ -\partial^2 \eta_{\mu \nu} + \partial_\mu \partial_\nu \left( 1 - \frac{1}{\xi} \right) \right] A^{\nu b}. \]  

We can invert to find the propagator. In momentum space:

\[ D_{\mu \nu} = -\frac{\eta_{\mu \nu} + (\xi - 1)k_\mu k_\nu / k^2}{k^2 + i \epsilon}. \]  

To write explicit Feynman rules, we need also to deal with the Faddeev–Popov determinant. Feynman long ago guessed that the unitarity problems of Yang–Mills theories could be dealt with by introducing fictitious scalar fields with the wrong statistics. Our expression for \( \Delta \) can be reproduced by a functional integral for such particles:

\[ \Delta = \int [dc^a][dc^{a\dagger}] \exp \left( i \int d^4x (c^{a\dagger} \partial^2 \delta_{ab} + f^{abc} A^{\mu c} \partial_\mu c^b) \right). \]  

From here, we can read off the Feynman rules for Yang–Mills theories, including matter fields. These are summarized in Fig. 2.3.

### 2.3.1 Gauge fixing in theories with broken gauge symmetry

Gauge fixing in theories with broken gauge symmetries raise some new issues. We consider first a \( U(1) \) gauge theory with a single charged scalar field, \( \phi \). We suppose that the potential is such that \( \langle \phi \rangle = v/\sqrt{2} \). We call \( e \) the gauge coupling and take the conventional scaling for the gauge kinetic terms. We can, again, parameterize the field as:

\[ \phi = \frac{1}{\sqrt{2}(v + \sigma(x))} e^{i\pi v}. \]  

Then we can again choose a gauge in which \( \pi(x) = 0 \). This gauge is known as unitary gauge, since, as we have seen, in this gauge we have exactly the degrees of freedom.
2.3 The quantization of Yang–Mills theories

\[ a \rightarrow b \kern-1em \, _{k \rightarrow} \, i \rightarrow j \left( i / p \delta_{ij} \right) = ig\gamma^\mu t^a \]

\[ b, v \kern-1em \, _{p \rightarrow} \, a, \mu \kern-1em \, _{c, \rho \rightarrow} \, k \rightarrow \, d, \sigma = g \left[ f^{abc} \left( g^{\mu \nu (k - p)\rho} + g^{\nu \rho (p - q)^\mu} + g^{\rho \mu (q - k)^\nu} \right) \right] \]

\[ a \rightarrow b \kern-1em \, _{p \rightarrow} \, b, \mu = i \delta^{ab} / p^2 \]

\[ p \kern-1em \, _{a \rightarrow} \, b, \mu = -gf^{abc} p^\mu \]

Fig. 2.3. Feynman rules for Yang–Mills theory.

freedom we expect physically: a massive gauge boson and a single real scalar. But this gauge is not convenient for calculations. The gauge boson propagator in this gauge is:

\[ \langle A_\mu A_\nu \rangle = -\frac{i}{k^2 - M_V^2} \left( \eta_{\mu \nu} - \frac{k_\mu k_\nu}{M_V^2} \right) \quad (2.58) \]

Because of the factors of momentum in the second term, individual Feynman diagrams have bad high-energy behavior. A more convenient set of gauges, known as \( R_\xi \) gauges, avoids this difficulty, at the price of keeping the \( \pi \) field (sometimes misleadingly called the Goldstone particle) in the Feynman rules. We take, in the path integral, the gauge-fixing function:

\[ G = \frac{1}{\sqrt{\xi}} \left( \partial_\mu A^\mu \xi - e \nu \pi(x) \right) \quad (2.59) \]

The extra term has been judiciously chosen so that when we exponentiate, the \( A^\mu \partial_\mu \pi \) terms in the action cancel. Explicitly, we have:

\[ \mathcal{L} = -\frac{1}{2} A_\mu \left( \eta^{\mu \nu} \partial^2 - \left( 1 - \frac{1}{\xi} \right) \partial^\mu \partial^\nu - (e^2 \nu^2 / 2) \eta^{\mu \nu} \right) A_\nu \quad (2.60) \]

\[ + \frac{1}{2} (\partial_\mu \pi)^2 - \frac{1}{2} m_\pi^2 \sigma^2 + \frac{1}{2} (\partial_\mu \pi)^2 - \frac{\xi}{2} (ev)^2 \pi^2 + \mathcal{O}(\phi^3). \]
If we choose $\xi = 1$ (‘t Hooft–Feynman gauge), the propagator for the gauge boson is simply

$$\langle A_\mu A_\nu \rangle = \frac{-i}{k^2 - M^2} \eta_{\mu\nu} \quad (2.61)$$

with $M^2 = e^2 v^2$, but we have also the field $\pi$ explicitly in the Lagrangian, and it has propagator:

$$\langle \pi \pi \rangle = \frac{i}{k^2 - M^2_V}. \quad (2.62)$$

The mass here is just the mass of the vector boson (for other choices of $\xi$, this is not true).

This gauge choice is readily extended to non-Abelian theories, with similar results: the gauge bosons have simple propagators, like those of massive scalars multiplied by $\eta_{\mu\nu}$. The Goldstone bosons appear explicitly in perturbation theory, with propagators appropriate to massive fields. The Faddeev–Popov ghosts have couplings to the scalar fields.

### 2.4 The particles and fields of the Standard Model

We are now in a position to write down the Standard Model. It is amazing that, at a microscopic level, almost everything we know about nature is described by such a simple structure. The gauge group is $SU(3)_c \times SU(2)_L \times U(1)_Y$. The subscript $c$ denotes color, $L$ means “left-handed” and $Y$ is called hypercharge. Corresponding to these different gauge groups, there are gauge bosons, $A^a_\mu$, $a = 1, \ldots, 8$, $W^i_\mu$, $i = 1, 2, 3$, and $B_\mu$.

One of the most striking features of the weak interactions is the violation of parity. In terms of four-component fields, this means that factors of $(1 - \gamma_5)$ appear in the couplings of fermions to the gauge bosons. In such a situation, it is more natural to work with two-component spinors. For the reader unfamiliar with such spinors, a simple introduction appears in Appendix A. Such spinors are the basic building blocks of the four-dimensional spinor representations of the Lorentz group. All spinors can be described as two-component spinors, with various quantum numbers. For example, quantum electrodynamics, which is parity invariant with a massive fermion, can be described in terms of two left-handed fermions, $e$ and $\bar{e}$, with electric charge $-e$ and $+e$, respectively. The Lagrangian takes the form:

$$\mathcal{L} = ie\sigma^\mu D_\mu e^* + i\bar{e}\sigma^\mu D_\mu \bar{e}^* - m \bar{e}e - m^* \bar{e}^* e^*. \quad (2.63)$$
The covariant derivatives are those appropriate to fields of charge $e$ and $-e$. Parity is the symmetry $\vec{x} \rightarrow -\vec{x}, e \leftrightarrow \bar{e}^*$, and $\vec{A} \rightarrow -\vec{A}$.

We can specify the fermion content of the Standard Model by giving the gauge quantum numbers of the left-handed spinors. So, for example, there are quark doublets which are $3s$ of color and doublets of $SU(2)$, with hypercharge $1/3$: $Q = (3, 2)_{1/3}$. The appropriate covariant derivative is:

$$D_\mu Q = \left( \partial_\mu - ig_s A_\mu^a T^a - ig W^i_\mu T^i - ig' B_\mu \right) Q.$$ (2.64)

Here $T^i$ are the generators of $SU(2)$, $T^i = \sigma^i/2$. These are normalized as

$$\text{Tr}(T^i T^j) = \frac{1}{2} \delta^{ij}. \quad (2.65)$$

The $T^a$ are the generators of $SU(3)$; in terms of Gell-Mann’s $SU(3)$ matrices, $T^a = \lambda^a/2$. They are normalized like the $SU(2)$ matrices, $\text{Tr} T^a T^b = (1/2) \delta^{ab}$.

We have followed the customary definition, in coupling $B_\mu$ to half the hypercharge current. We have also scaled the fields so that the couplings appear in the covariant derivative, and labeled the $SU(3)_c, SU(2)_L$, and $U(1)_Y$ coupling constants as $g_s, g$ and $g'$, respectively. Using matrix-valued fields, defined with the couplings in front of the gauge kinetic terms, this covariant derivative can be written in a very compact manner:

$$D_\mu Q = \left( \partial_\mu - i A_\mu - i W^i_\mu T^i - \frac{i}{2} B_\mu \right) Q. \quad (2.66)$$

As another example, the Standard Model contains lepton fields, $L$, with no $SU(3)$ quantum numbers, but which are $SU(2)$ doublets with hypercharge $-1$. The covariant derivative is:

$$D_\mu L = \left( \partial_\mu - i g W^i_\mu T^i - \frac{g'}{2} B_\mu \right) L. \quad (2.67)$$

Similarly for the Higgs doublet, $\phi$.

So we can summarize the fermion contact in the Standard Model with the following data:

<table>
<thead>
<tr>
<th></th>
<th>$SU(3)$</th>
<th>$SU(2)$</th>
<th>$U(1)_Y$</th>
</tr>
</thead>
<tbody>
<tr>
<td>$Q_f$</td>
<td>3</td>
<td>2</td>
<td>1/3</td>
</tr>
<tr>
<td>$\bar{u}_f$</td>
<td>$\frac{3}{2}$</td>
<td>1</td>
<td>$-4/3$</td>
</tr>
<tr>
<td>$\bar{d}_f$</td>
<td>3</td>
<td>1</td>
<td>2/3</td>
</tr>
<tr>
<td>$L_f$</td>
<td>1</td>
<td>2</td>
<td>$-1$</td>
</tr>
<tr>
<td>$\bar{e}_f$</td>
<td>1</td>
<td>1</td>
<td>2</td>
</tr>
</tbody>
</table>
Here \( f \) labels the quark or lepton flavor, or generation number, \( f = 1, 2, 3 \). For example,

\[
L_1 = \begin{pmatrix} \nu_e \\ e \end{pmatrix}, \quad L_2 = \begin{pmatrix} \nu_\mu \\ \mu \end{pmatrix}, \quad L_3 = \begin{pmatrix} \nu_\tau \\ \tau \end{pmatrix}.
\]

(2.69)

Why there is this repetitive structure, these three generations, is one of the great puzzles of the Standard Model, to which we will return. In terms of these two-component fields (indicated generically by \( \psi_i \)), the gauge-invariant kinetic terms have the form:

\[
L_{f,k} = -i \sum_i \psi_i D_\mu \sigma^\mu \psi^*_i
\]

(2.70)

where the covariant derivatives are those appropriate to the representation of the gauge group.

Unlike QED (where, in two-component language, parity interchanges \( e \) and \( \bar{e}^* \)), the model does not have a parity symmetry. The fields \( Q \) and \( \bar{u}, \bar{d} \) transform under different representations of the gauge group. There is simply no discrete symmetry one can find which is the analog of the parity symmetry of QED.

In order to account for the masses of the \( W \) and \( Z \) bosons and the quarks and leptons, the simplest version of the Standard Model includes a scalar, \( \phi \), which transforms as a \((1,2)_1\) of the Standard Model gauge group. This Higgs field possesses both self-couplings and Yukawa couplings to the fermions. Its kinetic term is simply

\[
L_{\phi,k} = |D_\mu \phi|^2.
\]

(2.71)

The Higgs potential is similar to that of our toy model:

\[
V(\phi) = \mu^2 |\phi|^2 + \lambda |\phi|^4.
\]

(2.72)

This is completely gauge invariant. But if \( \mu^2 \) is negative, the gauge symmetry breaks as before. We will describe this breaking, and the mass matrix of the gauge bosons, shortly. At this point, we have written the most general renormalizable self-couplings of the scalar fields. Renormalizability and gauge invariance permit one other set of couplings in the Standard Model: Yukawa couplings of the scalars to the fermions. The most general such couplings are:

\[
L_{\text{Yuk}} = y_U^{f,f} Q_f \bar{u}_f \sigma^2 \phi^* + y_D^{f,f} Q_f \bar{d}_f \phi + y_L^{f,f} L_f \bar{e}_f \phi.
\]

(2.73)

Here \( y_U, y_D \) and \( y_L \) are general matrices in the space of flavors.

We can simplify the Yukawa coupling matrices significantly by redefining fields. Any \( 3 \times 3 \) matrix can be diagonalized by separate left and right \( U(3) \) matrices. To
see this, suppose one has some matrix, \( M \), not necessarily Hermitian. The matrices:

\[
A = MM^\dagger \quad B = M^\dagger M
\]  

(2.74)

are Hermitian matrices. \( A \) can be diagonalized by a unitary transformation, \( U_L \), say, and \( B \) by a unitary transformation \( U_R \). Then the matrices:

\[
U_L M U_R^\dagger \quad U_R M^\dagger U_L^\dagger
\]  

(2.75)

are diagonal. So by redefining fields, we can simplify the matrices \( y^U \), \( y^D \) and \( y^L \); it is customary to take \( y^U \) and \( y^L \) diagonal. There is a conventional form for \( y^D \) (the Cabibbo–Kobayashi–Maskawa matrix) which we will describe in Section 3.2.

To summarize, the entire Lagrangian of the Standard Model consists of the following.

1. Gauge-invariant kinetic terms for the gauge fields,

\[
\mathcal{L}_a = -\frac{1}{4g_s^2} G_{\mu\nu}^2 - \frac{1}{4g^2} W_{\mu\nu}^2 - \frac{1}{4g'^2} F_{\mu\nu}^2
\]  

(2.76)

(here we have returned to our scaling with the couplings in front; \( G_{\mu\nu}, W_{\mu\nu}, \) and \( F_{\mu\nu} \) are the \( SU(3), SU(2) \) and \( U(1) \) field strengths).

2. Gauge-invariant kinetic terms for the fermion and Higgs fields, \( \mathcal{L}_{f,k}, \mathcal{L}_{\phi,k} \).

3. Yukawa couplings of the fermions to the Higgs field, \( \mathcal{L}_{Yuk} \).

4. The potential for the Higgs field, \( V(\phi) \).

If we require renormalizability, i.e. we require that all of the terms in the Lagrangian be of dimension four or less, this is all we can write. It is extraordinary that this simple structure incorporates over a century of investigation of elementary particles.

### 2.5 The gauge boson masses

The field \( \phi \) has an expectation value, which we can take to have the form:

\[
\langle \phi \rangle = \frac{1}{\sqrt{2}} \begin{pmatrix} 0 \\ v \end{pmatrix}
\]  

(2.77)

where \( v = \mu/\sqrt{\lambda} \). Expanding around this expectation value, the Higgs field can be written as:

\[
\phi = e^{i\tilde{\pi}(x)\tilde{\sigma}/2v} \frac{1}{\sqrt{2}} \begin{pmatrix} 0 \\ v + \sigma(x) \end{pmatrix}.
\]  

(2.78)
By a gauge transformation, we can set $\vec{\pi} = 0$. Not all of the gauge symmetry is broken by $\langle \phi \rangle$. Note that $\langle \phi \rangle$ is invariant under the $U(1)$ symmetry generated by

$$Q = T_3 + \frac{Y}{2}. \quad (2.79)$$

This is the electric charge. If we write:

$$L = \begin{pmatrix} \nu \\ e \end{pmatrix} \quad Q = \begin{pmatrix} u \\ d \end{pmatrix} \quad (2.80)$$

then the $\nu$ has charge 0, and $e$ has charge $-1$; $u$ has charge $2/3$, $d$ charge $-1/3$. The charges of the singlets also work out correctly.

With this gauge choice, we can examine the scalar kinetic terms in order to determine the gauge boson masses. Keeping only terms quadratic in fluctuating fields ($\sigma$ and the gauge fields), these now have the form:

$$|D_\mu \phi|^2 = \frac{1}{2} (\partial_\mu \sigma^2) + (0 \nu) \left( igW^i_\mu \frac{\sigma^i}{2} + \frac{ig'}{2} B_\mu \right) \left( -igW^j_\mu \frac{\sigma^j}{2} - \frac{ig'}{2} B^\mu \right) \begin{pmatrix} 0 \\ \nu \end{pmatrix}. \quad (2.81)$$

It is convenient to define the complex fields:

$$W^{\pm}_\mu = \frac{1}{\sqrt{2}} \left( W^1_\mu \pm i W^2_\mu \right) \quad (2.82)$$

These are states of definite charge, since they carry zero hypercharge and $T_3 = \pm 1$. In terms of these fields, the gauge boson mass and kinetic terms take the form:

$$\partial_\mu W^+ W^- + \frac{1}{2} \partial_\mu W^3 \partial^\mu W^3 + \frac{1}{2} \partial_\mu B_v \partial^\mu B_v + g^2 v^2 W^\mu W^- + \frac{1}{2} v^2 (g W^3_\mu - g' B_\mu)^2. \quad (2.83)$$

Examining the terms involving the neutral fields, $B_\mu$ and $W^3_\mu$, it is natural to redefine:

$$A_\mu = \cos(\theta_w) B_\mu + \sin(\theta_w) W^3_\mu; \quad Z_\mu = \sin(\theta_w) B_\mu + \cos(\theta_w) W^3_\mu \quad (2.84)$$

where

$$\sin(\theta_w) = \frac{g'}{\sqrt{g^2 + g'^2}} \quad (2.85)$$

is known as the Weinberg angle. The field $A_\mu$ is massless, while the $W$s and $Z$s have masses:

$$M^2_W = g^2 v^2 \quad M^2_Z = (g^2 + g'^2) v^2 = M^2_W / \cos^2(\theta_w). \quad (2.86)$$
We can immediately see that $A_\mu$ couples to the current:

$$j_{\text{em}}^\mu = g' \cos(\theta_w) \frac{1}{2} j_\mu^Y + g \sin(\theta_w) j_\mu^3 = e \left[ \frac{1}{2} j_\mu^Y + j_\mu^3 \right],$$  \hspace{1cm} (2.87)

where

$$e = \frac{gg'}{\sqrt{g^2 + g'^2}}$$  \hspace{1cm} (2.88)

is the electric charge. So $A_\mu$ couples precisely as we expect the photon to couple. $W^{\mu \pm}$ couple to the charged currents of the four-fermi theory. The $Z$ boson couples to:

$$j_{Z}^\mu = -g' \sin(\theta_w) \frac{1}{2} j_\mu^Y + g \cos(\theta_w) j_\mu^3.$$ \hspace{1cm} (2.89)

### 2.6 Quark and lepton masses

Substituting the expectation value for the Higgs fields into the expression for the quark and lepton Yukawa couplings, Eq. (2.73) leads directly to masses for the quarks and leptons. The lepton masses and the masses for the up quarks are immediate:

$$m_{Uf} = y_{Uf} \frac{v}{\sqrt{2}}, \quad m_{Ef} = y_{Ef} \frac{v}{\sqrt{2}}.$$ \hspace{1cm} (2.90)

So, for example, the Yukawa coupling of the electron is $(m_e \sqrt{2})/v$.

But the masses for the $d$ quarks are somewhat more complicated. Because $y_D$ is not diagonal, we have a matrix, in flavor space, for the $d$ quark masses:

$$(m_D)_{ff'} = (y_D)_{ff'} \frac{v}{\sqrt{2}}.$$ \hspace{1cm} (2.91)

As we have seen, any matrix can be diagonalized by separate unitary transformations acting on the left and the right. So we can diagonalize this by separate rotations of the $D$ quarks (within the quark doublets) and the $\bar{D}$ quarks. The rotation of the $\bar{D}$ quarks is just a simple redefinition of these fields. But the rotation of the $D$ quarks is more significant, since it does not commute with $SU(2)_L$. In other words, the quark masses are not diagonal in a basis in which the $W$ boson couplings are diagonal. The basis in which the mass matrix is diagonal is known as the mass basis (the corresponding fields are often called “mass eigenstates”).

The unitary matrix acting on the $D$ quarks is known as the Cabibbo–Kobayashi–Maskawa, or CKM, matrix. In terms of this matrix, the coupling of the quarks to
the $W^\pm$ fields can be written:

$$W^-_\mu U_f \sigma^\mu D_f^* V_{ff'} + W^+_\mu D_f \sigma^\mu U_f^* V_{ff'}^*.$$  \hfill (2.92)

There are a variety of parameterizations of $V$, which we will discuss shortly. One interesting feature of the model is the $Z$ couplings. Because $V$ is unitary, these are diagonal in flavor. This explains why $Z$ bosons don’t mediate processes which change flavor, such as $K_L \rightarrow \mu^+ \mu^-$. The suppression of these *flavor-changing neutral currents* was one of the early, and critical, successes of the Standard Model.

**Suggested reading**

There are a number of textbooks with good discussions of the Standard Model, including those of Peskin and Schroeder (1995), Weinberg (1995), Cottingham and Greenwood (1998), Donoghue *et al.* (1992) and Seiden (2005). We cannot give a full bibliography of the Standard Model here, but the reader may want to examine some of the original papers, including: Yang and Mills (1954), Salam and Ward (1964), Weinberg (1967) and Glashow *et al.* (1970) on the weak interaction theory; ’t Hooft (1971), Gross and Wilczek (1973) and Politzer (1973) on asymptotic freedom of the strong interactions. For discussion of the phases of gauge theories, see ’t Hooft (1980) and Fradkin and Shenker (1979).

**Exercises**

1. Georgi–Glashow Model: consider a gauge theory based on $SU(2)$, with Higgs field, $\vec{\phi}$, in the adjoint representation. Assuming that $\phi$ obtains an expectation value, determine the gauge boson masses. Identify the photon and the $W^\pm$ bosons. Is there a candidate for the $Z$ boson?

2. Consider the Standard Model with two generations. Show that there is no CP violation, and show that the KM matrices can be described in terms of a single angle, known as the Cabibbo angle.
3

Phenomenology of the Standard Model

The predictions of the Standard Model have been subjected to experimental tests in a broad range of processes. In processes involving leptons alone, and hadrons at high-momentum transfers, detailed, precise predictions are possible. In processes involving hadrons at low momentum, it is often possible to make progress using symmetry arguments. In still other cases, one can at least formulate a qualitative picture. In recent years, developments in lattice gauge theory have begun to offer the promise of reliable and precise predictions for at least some features of the large-distance behavior of hadrons. There exist excellent texts and reviews treating all of these topics. Here we will give only a brief survey, attempting to introduce ideas and techniques which are important in understanding what may lie beyond the Standard Model.

3.1 The weak interactions

We are now in a position to describe the weak interactions within the Standard Model. Summarizing our results for the $W$ and $Z$ masses, we have, at the tree level:

$$M_W^2 = \frac{\pi \alpha}{\sqrt{2} G_F \sin^2 \theta_w}, \quad M_Z^2 = \frac{\pi \alpha}{\sqrt{2} G_F \sin^2 \theta_w \cos^2 \theta_w},$$

(3.1)

where $\alpha$ is the fine-structure constant. Note, in particular, that in the leading approximation,

$$\frac{M_W^2}{M_Z^2} = \cos^2 \theta_w.$$

(3.2)

In these expressions, the Fermi constant is related to the $W$ mass and the gauge coupling through:

$$G_F = \sqrt{2} \frac{g^2}{8 M_W^2}, \quad G_F = 1.166 \times 10^{-5} \text{ GeV}^{-2}.$$

(3.3)
The Weinberg angle is:
\[ \sin^2(\theta_w) = 0.23120(15). \]  
(3.4)

The measured values of the \( W \) and \( Z \) masses are:
\[ M_W = 80.425(38) \text{ GeV} \quad M_Z = 91.1876(21) \text{ GeV}. \]  
(3.5)

One can see that the experimental quantities satisfy the theoretical relations to good accuracy. They are all in agreement at the part in \( 10^{-2} \)–\( 10^{-3} \) level when radiative corrections are included.

The effective Lagrangian for the quarks and leptons obtained by integrating out the \( W \) and \( Z \) particles is:
\[ L_W + L_Z = \frac{8G_F}{\sqrt{2}} \left[ (J^1_\mu)^2 + (J^2_\mu)^2 + (J^3_\mu - \sin^2 \theta_w J_{\mu \text{EM}})^2 \right]. \]  
(3.6)

The first two terms correspond to the exchange of the charged \( W^\pm \) fields. The last term represents the effect of \( Z \) boson exchange. This structure has been tested extensively. In many experiments, the precision is sufficiently great that it is necessary to include radiative corrections.

The most precise tests of the weak interaction theory involve the \( Z \) bosons. Experiments at the LEP accelerator at CERN and the SLD accelerator at SLAC produced millions of \( Z \)s. These large samples permitted high-precision studies of the line shape and of the branching ratios to various final states. Care is needed in calculating radiative corrections. It is important to make consistent definitions of the various quantities. Detailed comparisons of theory and experiment can be found on the web site of the Particle Data Group (http://pdg.lbl.gov). As inputs, one generally takes the value of \( G_F \) measured in \( \mu \) decays; the measured mass of the \( Z \), and the fine structure constant. Outputs include the \( Z \) boson total width:

\[ \text{experiment} \quad \Gamma_Z = 2.4952 \pm 0.0023 \quad \text{theory} \quad \Gamma_Z = 2.4956 \pm 0.0007. \]  
(3.7)

The decay width of the \( Z \) to hadrons and leptons is also in close agreement (see Fig. 3.1). The \( W \) mass can also be computed with these inputs, and is by now measured quite precisely:

\[ \text{experiment} \quad M_W = 80.454 \pm 0.059 \pm 0.0023 \quad \text{theory} \quad M_W = 80.390 \pm 0.18. \]  
(3.8)

As of this writing, one piece of the Standard Model is missing: the Higgs boson. Taking seriously the simplest version of symmetry breaking in the Standard Model, there is one additional physical state. Its mass is a parameter (e.g. knowing the value of \( G_F \), it can be determined in terms of the Higgs quartic coupling, \( \lambda \)). Finding the Higgs particle is a serious experimental challenge, as its couplings to most particles
3.1 The weak interactions

Fig. 3.1. OPAL results for the Z line shape. The solid line is theory; the dots are data (the size of the dots corresponds to the size of the error bars).

![Graph showing OPAL results for the Z line shape.](image)

Fig. 3.2. Higgs can be produced in $e^+e^-$ annihilation in association with a $Z^0$ particle.

![Diagram showing Higgs production in $e^+e^-$ annihilation.](image)

are quite small. For example, couplings to leptons are suppressed by $m_\ell/v$. The LEP experiments set a lower limit on the Higgs mass of about 115 GeV. The principal production mechanism is indicated in Fig. 3.2. For Higgs in the mass range explored at LEP, the most important decay channel involves decays to $b$ quarks. At the LHC, other production mechanisms are dominant. For example, for a broad range of
masses, colliding gluons produce a virtual top pair, which in turn couple to the Higgs (Fig. 3.3).

### 3.2 The quark and lepton mass matrices

We have seen that we can take the Yukawa couplings for the up-type quarks to be diagonal, but cannot simultaneously diagonalize those for the down-type quarks. As a result, when the Higgs field gets an expectation value, the up quark masses are given by:

\[ m_{uf} = \frac{(y_u)_f}{\sqrt{2}} v. \]  

These are automatically diagonal. But the down quark masses are described by a $3 \times 3$ mass matrix,

\[ m_{dff'} = \frac{(y_d)_{ff'}}{\sqrt{2}} v. \]  

We can diagonalize this matrix by separate unitary transformations of the $\bar{d}$ and $d$ fields. Because the $d$ quarks are singlets of $SU(2)$, the transformation of $\bar{d}$ leaves the kinetic terms and gauge interactions of these quarks unchanged. But the transformation of the $d$ quarks does not commute with $SU(2)$, so the couplings of the gauge bosons to these quarks are more complicated. The unitary transformation between the “mass” or “flavor” eigenstates and the weak interaction eigenstates is known as the CKM matrix. Denoting the mass eigenstates as $u'$, $d'$, etc., the
3.2 The quark and lepton mass matrices

The quark and lepton mass matrices have the form:

\[
\begin{pmatrix}
  d' \\
  s' \\
  b'
\end{pmatrix} =
\begin{pmatrix}
  V_{ud} & V_{us} & V_{ub} \\
  V_{cd} & V_{cs} & V_{cb} \\
  V_{td} & V_{ts} & V_{tb}
\end{pmatrix}
\begin{pmatrix}
  d \\
  s \\
  b
\end{pmatrix}.
\]  

(3.11)

There are various ways of parameterizing the CKM matrix. The Particle Data Group favors the following convention:

\[
V =
\begin{pmatrix}
  c_{12}c_{13} & s_{12}c_{13} & s_{13}e^{-i\delta_{13}} \\
  -s_{12}c_{23} - c_{12}s_{23}s_{13}e^{i\delta_{13}} & c_{12}c_{23} - s_{12}s_{23}s_{13}e^{i\delta_{13}} & s_{23}s_{13} \\
  s_{12}s_{23} - c_{12}c_{23}s_{13}e^{i\delta_{13}} & -c_{12}s_{23} - s_{12}c_{23}s_{13}e^{i\delta_{13}} & c_{23}s_{13}
\end{pmatrix}.
\]  

(3.12)

A number of features of this parameterization are worthy of note. First, \( V \) is unitary, \( V^*V = 1 \). Second, \( V \) is real unless \( \delta \) is non-zero. Thus \( \delta \) provides a measure of CP violation. Finally, the parameterization has been chosen in such a way that, experimentally, all of the angles are small. As a result, all of the off-diagonal components of the matrix are small. The current measured values of the CKM angles are:

\[
s_{12} = 0.2243 \pm 0.0016 \\
s_{23} = 0.0413 \pm 0.0015 \\
s_{13} = 0.0039 \pm 0.0005 \\
\delta_{13} = 1.05 \pm 0.024.
\]  

(3.13)

Examining these quantities, one sees that not only are the off-diagonal matrix elements small, but they are hierarchically small. Wolfenstein has developed a convenient parameterization:

\[
V =
\begin{pmatrix}
  1 - \lambda^2 / 2 & \lambda & A\lambda^3(\rho - i\eta) \\
  -\lambda & 1 - \lambda^2 / 2 & A\lambda^2 \\
  A\lambda^3(1 - \rho - i\eta) & -A\lambda^2 & 1
\end{pmatrix} + O(\lambda^4).
\]  

(3.14)

Note that \( \delta_{13} \), and hence \( \rho \) and \( \eta \), are not small. But there are several small entries, and a hierarchical structure reminiscent of the quark masses themselves.

From unitarity follow a number of relations among the elements of the matrix. For example,

\[
V_{ud}V_{ub}^* + V_{cd}V_{cb}^* + V_{td}V_{tb}^* = 0.
\]  

(3.15)

From \( V_{ud} \approx V_{ub} \approx V_{ib} \approx 1 \), this becomes a relation between three complex numbers which says that they form a triangle – the unitarity triangle. Determining from experiment that these quantities do form a triangle is an important test of this model for the quark masses.

We should also give the values of the quark masses themselves. This is somewhat subtle, since in QCD it is necessary to specify an energy scale, much as one must specify the scale of the gauge coupling in QCD. With a scale of order 1 GeV, the
quark masses are roughly:

$$m_u \approx 1.5 - 4 \text{ MeV} \quad m_d \approx 4 - 8 \text{ MeV} \quad m_s \approx 80 - 130 \text{ MeV}$$
$$m_c \approx 1.15 - 1.35 \text{ GeV} \quad m_b \approx 4.1 - 4.4 \text{ GeV} \quad m_t \approx 174.3 \pm 5 \text{ GeV}.$$  (3.16)

Before considering the small neutrino masses, the lepton Yukawa couplings can simply be taken diagonal, and there is no mixing. The lepton masses are:

$$m_e = 0.511 \text{ MeV} \quad m_\mu = 113 \text{ MeV} \quad m_\tau = 1.777 \text{ GeV}.$$  (3.17)

Overall, the picture of quark and lepton masses is quite puzzling. They vary over nearly five orders of magnitude. Correspondingly, the dimensionless Yukawa couplings have widely disparate values. Understanding this might well be a clue to what lies beyond the Standard Model.

### 3.3 The strong interactions

The strong interactions, as their name implies, are characterized by strong coupling. As a result, perturbative methods are not suitable for most questions. In comparing theory and experiment, it is necessary to focus on a few phenomena which are accessible to theoretical analysis. By itself, this is not particularly disturbing. A parallel with the quantum mechanics of electrons interacting with nuclei is perhaps helpful. We can understand simple atoms in detail; atoms with very large $Z$ can be treated by Hartree–Fock or other methods. But atoms with intermediate $Z$ can be dealt with, at best, by detailed numerical analysis accompanied by educated guesswork. Molecules are even more problematic, not to mention solids. But we are able to make detailed tests of the theory (and its extension in quantum electrodynamics) from the simpler systems, and develop qualitative understanding of the more complicated systems. In many cases, we can do quantitative analysis of the small fluctuations about the ground states of the complicated system.

In the theory of strong interactions, as we will see, many problems are hopelessly complicated. Low-lying spectra are hard; detailed exclusive cross sections in high-energy scattering essentially impossible. But there are many questions we can answer. Rates for many inclusive questions at very high energy and momentum transfer can be calculated with high precision. Qualitative features of the low lying spectrum of hadrons and their interactions at low energies can be understood in a qualitative (and sometimes quantitative) fashion by symmetry arguments. Recently, progress in lattice gauge theory has made it possible to perform calculations which previously seemed impossible, for features of spectra and even for interaction rates important for understanding the weak interactions.
The coupling of a gauge theory (and of a field theory more generally) is a function of energy or length scale. If a typical momentum transfer in a process is $q$, and if $M$ denotes the cutoff scale,

$$\frac{8\pi^2}{g^2(q^2)} = \frac{8\pi^2}{g^2(\Lambda)} + b_0 \ln \left( \frac{q^2}{M^2} \right).$$  \hspace{1cm} (3.18)

Here

$$b_0 = \frac{11}{3} C_A - \frac{2}{3} c_i n_f^{(i)} - \frac{1}{3} c_i n_\phi^{(i)}.$$  \hspace{1cm} (3.19)

In this expression, $n_f^{(i)}$ is the number of left-handed fermions in the $i$th representation, while $n_\phi^{(i)}$ is the number of scalars. $C_A$ is the quadratic Casimir of the adjoint representation, and $c_i$ the quadratic Casimir of the $i$th representation,

$$f^{acd} f^{bcd} = C_A \delta^{ab} \quad \text{Tr}(T^a T^b) = c_i \delta^{ab}.$$  \hspace{1cm} (3.20)

These formulas are valid if the masses of the fermions and scalars are negligible at scale $q^2$. For example, in QCD, at scales of order the $Z$ boson mass, the masses of all but the top quark can be neglected. All the quarks are in the fundamental representation, and there are no scalars. So $b_0 = 22/3$. As a result, $g^2$ gets smaller as $q^2$ gets larger, and, conversely, $g^2$ gets larger as $q^2$ gets smaller. Since momentum transfer is inversely proportional to a typical distance scale, one can say that the strong force gets weaker at short distances, and stronger at large distances. We will calculate $b_0$ in Section 3.5.

This is quite striking. In the case of QCD, it means that hadrons, when probed at very large momentum transfer, behave as collections of free quarks and gluons. Perturbation theory can be used to make precise predictions. On the other hand, viewed at large distances, hadrons are strongly interacting entities. Perturbation theory is not a useful tool, and other methods must be employed. The most striking phenomena in this regime are confinement – the fact that one cannot observe free quarks – and, closely related, the existence of a mass gap. Neither of these phenomena can be observed in perturbation theory.

### 3.4 The renormalization group

In thinking about physics beyond the Standard Model, by definition, we are considering phenomena involving degrees of freedom to which we have, as yet, no direct experimental access. The question of degrees of freedom which are as yet unknown is the heart of the problem of renormalization. In the early days of quantum field theory, it was often argued that one should be able to take a formal limit of infinite
cutoff, \( \Lambda \to \infty \). Ken Wilson promulgated a more reasonable view: real quantum field theories describe physics below some characteristic scale, \( \Lambda \). In a condensed matter system, this might be the scale of the underlying lattice, below which the system may often be described by a continuum quantum field theory. In the Standard Model, a natural scale is the scale of the \( W \) and \( Z \) bosons. Below this scale, the system can be described by a renormalizable field theory, QED plus QCD, along with certain non-renormalizable interactions – the four-fermi couplings of the weak interactions. In defining this theory, one can take the cutoff to be, say, \( M_W \), or one can take it to be \( aM_W \), for some \( a < 1 \). Depending on the choice of \( a \), the values of the couplings will vary. The parameters of the low energy effective Lagrangian must depend on \( a \) in such a way that physical quantities are independent of this choice. The process of determining the values of couplings in an effective theory which reproduce the effects of some more microscopic theory is often referred to as matching.

Knowing how physical couplings depend on the cutoff, one can determine how physical quantities behave in the long-wavelength, infrared regime by simple dimensional analysis. Quantities associated with operators of dimension less than four will grow in the infrared. They are said to be “relevant.” Those with dimension four will vary as powers of logarithms; they are said to be “marginal.” Quantities with dimension greater than four, those conventionally referred to as “non-renormalizable operators,” will be less and less important as the energy is lowered. They are said to be “irrelevant.” In strongly interacting theories, the dimensions of operators can be significantly different than expected from naive classical considerations. The classification of operators as relevant, marginal, and irrelevant applies to their quantum behavior.

At sufficiently low energies, we can ignore the irrelevant, non-renormalizable couplings. Alternatively, by choosing the matching scale, \( M \), low enough, only the marginal and relevant couplings are important. In a theory with only dimensionless couplings, the variation of the coupling with \( q^2 \) is closely related to its variation with the cutoff, \( M \). Physical quantities are independent of the cutoff, so any explicit dependence on the cutoff must be compensated by the dependence of the couplings on \( M \). On dimensional grounds, \( M \) must appear with \( q^2 \), so knowledge of dependence of couplings with \( M \) permits a derivation of their dependence on \( q^2 \). More precisely, in studying, say, a cross section, any explicit dependence on the cutoff must be compensated by the dependence of the coupling on the cutoff. Calling the physical quantity \( \sigma \), we can express this as a differential equation, the renormalization group equation:

\[
\left( M \frac{\partial}{\partial M} + \beta(g) \frac{\partial}{\partial g} \right) \sigma = 0. \tag{3.21}
\]
Here the beta function (or “$\beta$-function”) is given by:

$$\beta(g) = M \frac{\partial}{\partial M} g. \quad (3.22)$$

We can evaluate the beta function from our explicit expression, Eq. (3.18), for $g^2$:

$$\beta(g) = -b_0 \frac{g^2}{16\pi^2}. \quad (3.23)$$

We will compute $b_0$ in the next section. This equation has corrections in each order of perturbation theory and beyond.

So far we have expressed the coupling in terms of a cutoff and a physical scale. In an old-fashioned language, the coupling, $g^2(M)$, is the “bare” coupling. We can define a “renormalized coupling” at a scale $\mu^2$, $g^2(\mu)$:

$$\frac{8\pi^2}{g^2(\mu^2)} = \frac{8\pi^2}{g^2(M)} + b_0 \ln \left(\frac{\mu}{M}\right). \quad (3.24)$$

In practice, it is necessary to give a more precise definition. We will discuss this when we compute the beta function in the next section. Because of this need to give a precise definition of the renormalized coupling, care is required in comparing theory and experiment. There are, as we will review shortly, a variety of definitions in common use, and it is important to be consistent.

Quantities like Green’s functions are not physical, and obey an inhomogeneous equation. One can obtain this equation in a variety of ways. For simplicity, consider first a Green function with $n$ scalar fields, such as:

$$G(x_1, \ldots, x_n) = \langle \phi(x_1) \ldots \phi(x_n) \rangle. \quad (3.25)$$

This Green function is related to the renormalized Green function as follows. If the theory is defined at a scale $\mu$, the effective Lagrangian takes the form:

$$\mathcal{L}_\mu = Z^{-1}(\mu)(\partial\mu \phi^2) + \cdots. \quad (3.26)$$

Here $Z^{-1}$ arises from integrating out physics above the scale $\mu$. It will typically include ultraviolet-divergent loop effects. Rescaling $\phi$ so that the kinetic term is canonical, $\phi = Z^{1/2} \phi_r$, we have that

$$G(x_1, \ldots, x_n) = Z(\mu)^{n/2} G_r(x_1, \ldots, x_n). \quad (3.27)$$

The left-hand side is independent of $\mu$, so we can write an equation for $G_r$:

$$\left(\mu \frac{\partial}{\partial \mu} + \beta(g) \frac{\partial}{\partial g} + n \gamma\right) G_r = 0, \quad (3.28)$$

where $\gamma$, known as the anomalous dimension, is given by:

$$\gamma = \frac{1}{2} \mu \frac{\partial}{\partial \mu} \ln(Z). \quad (3.29)$$
In the case of several different fields, e.g. gauge fields, fermions and scalars, this equation is readily generalized. There is an anomalous dimension for each field, and the $n\gamma$ term is replaced by the appropriate number of fields of each type and their anomalous dimensions.

The effective action obeys a similar equation. Starting with:

$$\Gamma(x_1, \ldots, x_n) = Z(\mu)^{-n/2}\Gamma_r(x_1, \ldots, x_n).$$  \hspace{1cm} (3.30)

$$\left(\mu \frac{\partial}{\partial \mu} + \beta(g) \frac{\partial}{\partial g} - n\gamma\right) \Gamma_r = 0.$$  \hspace{1cm} (3.31)

These equations are readily solved. We could write the solution immediately, but an analogy with the motion of a fluid is helpful. A typical equation, for example, for the density of a component of the fluid (e.g. the density of bacteria) would take the form:

$$\left[ \frac{\partial}{\partial t} + v(x) \frac{\partial}{\partial x} - \rho(x) \right] D(t, x) = 0,$$  \hspace{1cm} (3.32)

where $D(t, x)$ is the density as a function of position and time, and $v(x)$ is the velocity of the fluid at $x$; $\rho$ represents a source term (e.g. growth due to the presence of yeast, or a variable temperature). To solve this equation, one first solves for the motion of an element of fluid initially at $x$, i.e. one solves:

$$\frac{d}{dt} \bar{x}(t; x) = v(\bar{x}(t; x)) \quad \bar{x}(0; x) = x.$$  \hspace{1cm} (3.33)

In terms of $\bar{x}$, we can immediately write down a solution for $D$:

$$D(t, x) = D_0(\bar{x}(t; x)) e^{\int_0^t dt' \int d^4 x' \rho(\bar{x}'(x'))}$$

$$\quad \quad = D_0(\bar{x}(t; x)) e^{\int_0^t dt' \int d^4 x' \frac{d\rho(\bar{x}'(x'))}{d\bar{x}'(x')} \bar{x}'(t; x')}.$$  \hspace{1cm} (3.34)

Here $D_0$ is the initial density. One can check this solution by plugging in directly, but each piece has a clear physical interpretation. For example, if there were no source ($\rho = 0$), the solution just would become $D_0(\bar{x}(t; x))$. With no velocity, the source would lead to just the expected growth of the density.

Let’s apply this to Green’s functions. Consider, for example, a two-point function, $G(p) = i\hbar(p^2/\mu^2)/p^2$. In our fluid dynamics analogy, the coupling, $g$, is the analog of the velocity; the log of the scale, $t = \ln(p/\mu)$, plays the role of the time. The equation for $g$ is then:

$$\left[ \frac{\partial}{\partial t} - \beta(g) \frac{\partial}{\partial g} - 2\gamma(g) \right] h(t) = 0.$$  \hspace{1cm} (3.35)
3.5 Calculating the beta function

Define $\bar{g}(\mu)$ as the solution of

$$\mu \frac{\partial}{\partial \mu} \bar{g}(\mu) = \beta(\bar{g}).$$ \hspace{1cm} (3.36)

At lowest order, this is solved by Eq. (3.24). Then

$$h(p, g) = h(\bar{g}(t))e^{\int_0^t dt' \gamma(\bar{g}(t', g))/\beta(\bar{g}(t'))}.$$ \hspace{1cm} (3.37)

One can write the solution in the form:

$$G(p, \lambda) = \frac{i}{p^2} G(\bar{g}(t; g))e^{\int_{\bar{g}}^{g} d\bar{g}' \gamma(\bar{g}')(\bar{g}(t', g)'})/\beta(\bar{g}(t', g')).$$ \hspace{1cm} (3.38)

### 3.5 Calculating the beta function

In the previous section, we presented the one loop result for the beta function and used it in various applications. In this section, we actually compute the beta function. There are a variety of ways to compute the variation of the gauge coupling with energy scale. One is to compute the potential for a very heavy quark–antiquark pair as a function of their separation (we use the term quark here loosely for a field in the $N$ representation of $SU(N)$). The potential is a renormalization-group invariant quantity. At lowest order it is given by:

$$V(R) = -\frac{g^2 C_F}{R}$$ \hspace{1cm} (3.39)

where

$$C_F = \sum_{a=1}^{N^2-1} T^a T^a.$$ \hspace{1cm} (3.40)

The potential is a physical quantity; this is why it is renormalization-group invariant. In perturbation theory, it has corrections behaving as $g^2(\Lambda) \ln(R\Lambda)$. This follows simply from dimensional analysis. So if we choose $R = \Lambda$, the logarithmic terms disappear and we have:

$$V(R) = -g^2(R) \frac{C_F}{R} (1 + O(g^2(R))).$$ \hspace{1cm} (3.41)

In an asymptotically free theory like QCD, where the coupling gets smaller with distance, Eq. (3.41) becomes more and more reliable as $R$ gets smaller. This result has physical applications. In the case of a bound state of a top quark and antiquark, one might hope that this would be a reasonable approximation, and describe the binding of the system. Taking $\alpha_s(R) \sim 0.1$, for example, would give a typical radius of order $(17 \text{ GeV})^{-1}$, a length scale where one might expect perturbation theory to be reliable (and for which $\alpha_s(R) \sim 0.1$). By analogy with the hydrogen atom, one
would expect the binding energy to be of order 2 GeV. In practice, however, this is not directly relevant, since the width of the top quark is of the same order – the top quark decays before it has time to form a bound state. Still, it should be possible to see evidence for such QCD effects in production of $t\bar{t}$ pairs near threshold in $e^+e^-$ annihilation.

A second approach is to study Green’s functions in momentum space. The calculation is straightforward, if slightly more tedious than the analogous calculation in a $U(1)$ gauge theory (QED). The main complication is the three gauge boson vertex, which has many terms (at one loop, one can use symmetries to greatly simplify the algebra). It is necessary to have a suitable regulator for the integrals. By far the most efficient is the dimensional regularization technique of ’t Hooft and Veltman. Here one initially allows the space-time dimensionality, $d$, to be arbitrary, and takes $d \rightarrow 4 - \epsilon$. For convenience, we include the two most frequently needed integration formulas below; their derivation can be found in many textbooks.

\[
\int \frac{d^d k}{(k^2 + M^2)^n} = \frac{\pi^{d/2} \Gamma(n - d/2)}{\Gamma(n)} (M^2)^{d/2-n} \quad (3.42)
\]

\[
\int \frac{d^d k^2}{(k^2 + M^2)^n} = \frac{\pi^{d/2} \Gamma(n - d/2 - 1)}{\Gamma(n)} (M^2)^{d/2-n+1}. \quad (3.43)
\]

Ultraviolet divergences, such as would occur for $n = 2$ in the first integral, give rise to poles in the limit $\epsilon \rightarrow 0$. If we were simply to cut off the integral at $k^2 = \Lambda^2$, we would find:

\[
\int \frac{d^4 k}{(2\pi)^4} \frac{1}{(k^2 + M^2)^2} \approx \frac{1}{16\pi^2} \ln(\Lambda/M). \quad (3.44)
\]

In dimensional regularization this behaves as:

\[
\int \frac{d^4 k}{(2\pi)^4} \frac{1}{(k^2 + M^2)^2} = \frac{1}{16\pi^2} \Gamma \left( \frac{\epsilon}{2} \right) \approx \frac{1}{8\pi^2\epsilon}. \quad (3.45)
\]

So $\epsilon$ should be thought of as $\ln(\Lambda^2)$. The computation of the Yang–Mills beta function by studying momentum-space Feynman diagrams can be found in many textbooks, and is outlined in the exercises.

Here we follow a different approach, known as the background field method. This technique is closely tied to the path integral, which will play an important role in this book. It is also closely tied to the Wilsonian view of renormalization. We break up $A$ into a long-wavelength part, and a shorter-wavelength, fluctuating quantum part:

\[
A^\mu = A^\mu + a^\mu. \quad (3.46)
\]
We can think of $A^\mu$ as corresponding to modes of the field with momenta below the scale $q$, and $a^\mu$ as corresponding to higher momenta. We wish to compute an effective action for $A^\mu$, integrating out the high-momentum modes:

$$\int [dA] \int [da] e^{i S(A,a)} = \int [dA] e^{i S_{\text{eff}}(A)}.$$  (3.47)

In calculating the effective action, we are treating $A^\mu$ as a fixed, classical background. In this approach, one can work entirely in Euclidean space, which greatly simplifies the calculation.

Our first task is to write $e^{i S(A,a)}$. For this purpose, it is convenient to suppose that $A$ satisfies its equation of motion. (Otherwise, it is necessary to introduce a source for $a$). A convenient choice of gauge is known as background field gauge:

$$D_\mu a^\mu = 0,$$  (3.48)

where $D_\mu$ is the covariant derivative defined with respect to the background field $A$. At one loop, we only need to work out the action to second order in the fluctuating fields $a^\mu, \psi, \phi$. Consider, first, the fermion action. To quadratic order, we can set $a^\mu = 0$ in the Dirac Lagrangian. The same holds for scalars. So from the fermions and scalars we obtain:

$$\det(\not{D})^{n_f} \det(D^2)^{-n_\phi/2}.$$  (3.49)

The fermion functional determinant can be greatly simplified. It is convenient, for this computation, to work with four-component Dirac fermions. Then

$$\det(\not{D}) = \det(\not{D})^{1/2} = \det \left( D^2 + \frac{1}{2} D_\mu D_\nu [\gamma^\mu, \gamma^\nu] \right) = \det(D^2 + F_{\mu\nu} J_{\mu\nu}).$$  (3.50)

Here $F_{\mu\nu}$ is the field strength associated with $A$ (we have used the connection of the field strength and the commutator of covariant derivatives, Eq. (2.14)), and $J_{\mu\nu}$ is the generator of Lorentz transformations in the fermion representation.

What is interesting is that we can write the gauge boson determinant, in the background field gauge, in a similar fashion.\(^1\) With a little algebra, the gauge part of the action can be shown to be

$$L_{\text{gauge}} = -\frac{1}{4g^2} \left( \text{Tr} F_{\mu\nu}^2 - 2 g^2 a^a_\mu D^2 a^\mu a^a - 2 a^a_\mu f^{abc} F_{\mu\nu} a^b_\nu a^c_\sigma \right).$$  (3.51)

\(^1\) The details of these computations are outlined in the exercises. Here we are following closely the presentation of the text by Peskin and Schroeder.
Here we have used the $A^a_\mu$ notation, in order to be completely explicit about the gauge indices. Recalling the form of the Lorentz generators for the vector representation:

$$ (\mathcal{J}^{\rho\sigma})_{a\beta} = i(\delta^\rho_a \delta^\sigma_\beta - \delta^\rho_\beta \delta^\sigma_a), \quad (3.52) $$

we see that this object has the same formal structure as the fermion action:

$$ \mathcal{L}_{\text{gauge}} = -\frac{1}{2g^2} \left[ a^a_\mu \left( -D^2 \right)^{ac} g^{\mu\nu} + 2 \left( \frac{1}{2} \mathcal{F}_{\rho\sigma}^{cb} \mathcal{J}^{\rho\sigma} \right) (t^b_\nu)^{ae} \right] a^c_\nu. \quad (3.53) $$

Finally, the Faddeev–Popov Lagrangian is just:

$$ \mathcal{L}_c = \bar{c}^a \left[ -\left( -D^2 \right)^{ab} \right] c^b. \quad (3.54) $$

Since the ghost fields are Lorentz scalars, this Lagrangian has the same form as the others. We need, then, to evaluate a product of determinants of the form:

$$ \det \left( -D^2 + 2 \left( \frac{1}{2} \mathcal{F}_{\rho\sigma}^{cb} \mathcal{J}^{\rho\sigma} \right) t^b \right) \quad (3.55) $$

with $t$ and $\mathcal{J}$ the generators appropriate to the representation.

The term in parentheses can be written:

$$ \Delta_{r,j} = -\partial^2 + \Delta^{(1)} + \Delta^{(2)} + \Delta^{(\mathcal{J})} \quad (3.56) $$

with

$$ \begin{align*}
\Delta^{(1)} &= i \left[ \partial^\mu A^a_\mu t^a + A^a_\mu t^a_\mu \partial^\mu \right] \\
\Delta^{(2)} &= A^a_\mu t^a_\mu A^a_\mu t^b_\nu. \\
\Delta^{(\mathcal{J})} &= 2 \left( \frac{1}{2} \mathcal{F}_{\rho\sigma}^{cb} \mathcal{J}^{\rho\sigma} \right) t^b.
\end{align*} \quad (3.57) $$

The action we seek is the log of the determinant. We are interested in this action expanded to second order in $A$ and second order in $\partial^2$:

$$ \ln \det(\Delta_{r,j}) = \ln \det(-\partial^2) + \text{tr} \left[ (-\partial^2)^{-1} (\Delta^{(1)} + \Delta^{(2)} + \Delta^{(\mathcal{J})}) \right. \\
- \frac{1}{2} \left( (-\partial^2)^{-1} \Delta^{(1)} (-\partial^2)^{-1} \Delta^{(1)} \right), \quad (3.58) $$

where $1/(-\partial^2)$ is the propagator for a scalar field. So this has the structure of a set of one-loop diagrams in a scalar field theory. Since we are working to quadratic order, we can take the $A$ to carry momentum $k$. The term involving two powers of $\Delta^{(1)}$ is in some ways the most complicated to evaluate. Note that the trace is a trace in coordinate space and on the gauge and Lorentz indices. In momentum space, the
3.6 The strong interactions and dimensional transmutation

In QCD, the only parameters, classically, with dimensions of mass are the quark masses. In a world with just two light quarks, $u$ and $d$, we wouldn’t expect the properties of hadrons to be different from the observed properties of the non-strange hadrons. But the masses of the up and down quarks are quite small, too small, as we
will see, to account for the masses of the non-strange hadrons, such as the proton and neutron. In other words, in the limit of zero quark mass, the hadrons would not become massless. How can a mass arise in a theory with no classical mass parameters?

While, classically, QCD is scale invariant, this is not true quantum mechanically. We have seen that we must specify the value of the gauge coupling at a particular energy scale; in the language we have used up to now, the theory is specified by giving the Lagrangian associated with a particular cutoff scale. If we change this scale, we have to change the values of the parameters, and physical quantities, such as the proton mass, should be unaffected. Using our experience with the renormalization group, we can write a differential equation which expresses how such a mass depends on $g$ and $\mu$ so that the mass is independent of which scale we choose for our Lagrangian:

$$\left[ \mu \frac{\partial}{\partial \mu} + \beta(g) \frac{\partial}{\partial g} \right] m_p = 0. \quad (3.63)$$

We know the solution of this equation:

$$m_p = C \mu e^{-\int \frac{dg}{\beta(g)}}. \quad (3.64)$$

To lowest order in the coupling,

$$m_p = C \mu e^{-\frac{8\pi^2}{\beta_0 g^2}}. \quad (3.65)$$

This phenomenon, that a physical mass scale can appear as a result of the need to introduce a cutoff in the quantum theory is called \textit{dimensional transmutation}. In the next section, we will discuss this phenomenon in lattice gauge theory. Later, we will describe a two-dimensional model in which we can do a simple computation which exhibits the dynamical appearance of a mass scale.

### 3.7 Confinement and lattice gauge theory

The fact that QCD becomes weakly coupled at high-momentum transfers has allowed rigorous comparison with experiment. Despite the fact that the variation of the coupling is only logarithmic, experiments are sufficiently sensitive, and have covered a sufficiently broad range of $q^2$, that such comparisons are possible. Still, many of the most interesting questions of hadronic physics – and some of the most interesting challenges of quantum field theory – are problems of low-momentum transfer. Here one encounters the flip side of asymptotic freedom: at large distances, the theory is necessarily strongly coupled and perturbative methods are not useful. It is, perhaps, frustrating that we cannot compute the masses of the low-lying hadrons in a fashion analogous to the calculation of the properties of simple atoms.
Perhaps even more disturbing is that we cannot give a simple argument that quarks are confined, or that QCD exhibits a mass gap. To deal with these questions, we can first ask a somewhat naive question: what can we say about the path integral, or for that matter the Hamiltonian, in the limit that the coupling constant becomes very large? This question is naive in that the coupling constant is not really a parameter of this theory. It is a function of scale, and the important scale for binding hadrons is the scale where the coupling becomes of order one. But let’s consider the problem anyway. Start with a pure gauge theory, i.e. a theory without fermions or scalars. Consider, first, the path integral. To extract the spectrum, it should be adequate to consider the Euclidean version:

\[ Z = \int [dA_{\mu}] \exp \left( -\frac{1}{4g^2} F_{\mu\nu}^2 \right). \]  

(3.66)

Let’s contrast the weak and strong coupling limits of this expression. At weak coupling, \( 1/g^2 \) is large, so fluctuations are highly damped; we might expect the action to be controlled by stationary points. The simplest such stationary point is just the one where \( F_{\mu\nu} = 0 \), and this is the basis of perturbation theory. Later we will see that there are other interesting stationary points – classical solutions of the Euclidean equations.

Now consider strong coupling. As \( g \rightarrow \infty \), the action vanishes – there is no damping of quantum fluctuations. It is not obvious how one can develop any sort of approximation scheme. We can consider this problem, alternatively, from a Hamiltonian point of view. A convenient gauge for this purpose is the gauge \( A_0 = 0 \). In this gauge, Gauss’s law is a constraint that must be imposed on states. As we will discuss shortly, Gauss’s law is (almost) equivalent to the condition that the quantum states must be invariant under time-independent gauge transformations. In \( A^0 = 0 \) gauge, the canonical momenta are very simple:

\[ \Pi^i = \frac{\partial L}{\partial \dot{A}^i} = -\frac{1}{g^2} E^i. \]  

(3.67)

So the Hamiltonian is:

\[ \mathcal{H} = \frac{g^2}{2} \Pi^2 + \frac{1}{2} \vec{B}^2. \]  

(3.68)

In the limit \( g^2 \rightarrow \infty \), the magnetic terms are unimportant, and the \( \Pi^2 \) terms dominate. So we should somehow work, in lowest order, with states which are eigenstates of \( \vec{E} \). In any approach which respects even rotational covariance, it is unclear how to proceed.

The solution to both dilemmas is to replace the continuum of space-time with a discrete lattice of points. In the Lagrangian approach, one introduces a space-time lattice. In the Hamiltonian approach, one keeps time continuous, but makes
space discrete. Clearly there is a large price for such a move: one gives up Lorentz
invariance – even rotational invariance. At best, Lorentz invariance is something
which one can hope to recover in the limit that the lattice spacing is small compared
to relevant physical distances. There are several rewards, however.

1. One has a complete definition of the theory which does not rely on perturbation theory.
2. The lattice, at strong coupling, gives a simple model of confinement.
3. One obtains a precise procedure in which to calculate properties of hadrons. With large
   enough computing power, one can in principle calculate properties of low-lying hadrons
   with arbitrary precision.

There are other difficulties. Not only is rotational symmetry lost, but other ap-
proximate symmetries – particularly chiral symmetries – are complicated. But over
time, combining ingenuity and growing computer power, there has been enormous
progress in numerical lattice computations. Lattice gauge theory has developed into
a highly specialized field of its own, and we will not do justice to it here. However,
given the importance of field theory – often strongly coupled field theories – not
only to our understanding of QCD but to any understanding of physics beyond the
Standard Model, it is worthwhile to briefly introduce the subject here.

3.7.1 Wilson’s formulation of lattice gauge theory

In introducing a lattice, the hope is that, as one takes the lattice spacing, \( a \), small,
one will recover Lorentz invariance. A little thought is required to understand what
is meant by \( small \). The only scale in the problem is the lattice spacing. But there will
be another important parameter: the gauge coupling. The value of this coupling, we
might expect, should be thought of as the QCD coupling at scale \( a \). So taking small
lattice spacing, physically, means taking the gauge coupling weak. At small lattice
spacing, short-distance Green’s functions will be well-approximated by their per-
turbative expansions. On the other hand, the smaller the lattice, the more numerical
power required to compute the physically interesting, long-distance quantities.

There is one symmetry which one might hope to preserve as one introduces a
space-time lattice: gauge invariance. Without it, there are many sorts of operators
which could appear in the continuum limit, and recovering the theory of interest
is likely to be very complicated. Wilson pointed out that there is a natural set
of variables to work with, the Wilson lines. Consider, first, a \( U(1) \) gauge theory.
Under a gauge transformation, \( A_\mu(x) \rightarrow A_\mu + i g(x) \partial_\mu g^\dagger(x) \), where \( g(x) = e^{i \alpha(x)} \),
the object

\[
U(x_1, x_2) = \exp \left( i \int_{x_1}^{x_2} dx_\mu A_\mu \right),
\]
transforms as:

\[ U(x_1, x_2) \rightarrow g(x_1)U(x_1, x_2)g^\dagger(x_2). \]  (3.69)

So, for example, for a charged fermion field, \( \psi(x) \), transforming as \( \psi(x) \rightarrow g(x)\psi(x) \), a gauge-invariant operator is:

\[ \psi^\dagger(x_1)U(x_1, x_2)\psi(x_2). \]  (3.70)

From gauge fields alone, one can construct an even simpler gauge-invariant object, a Wilson line beginning and ending at some point \( x \):

\[ U(x, x) = e^{i \int_c dx^\mu A_\mu}, \]  (3.71)

where \( U \) is called a Wilson loop.

These objects have a simple generalization in non-Abelian gauge theories. Using the matrix form for \( A_\mu \), the main issue is one of ordering. The required ordering prescription is path ordering, \( P \):

\[ U(x_1, x_2) = P e^{i \int_{x_1}^{x_2} dx^\mu A_\mu}. \]  (3.72)

It is not hard to show that the transformation law of the Abelian case generalizes to the non-Abelian case:

\[ U(x_1, x_2) \rightarrow g(x_1)U(x_1, x_2)g^\dagger(x_2). \]  (3.73)

To see this, note, first, that path ordering is like time ordering, so if \( s \) is the parameter of the path, \( U \) satisfies:

\[ \frac{d}{ds} U(x_1(s), x_2) = \left( ig \frac{dx^\mu}{ds} A_\mu(x_1(s)) \right) U(x_1(s)x_2), \]  (3.74)

or, more elegantly,

\[ \frac{dx^\mu_1}{ds} D_\mu U(x_1, x_2) = 0. \]  (3.75)

Now suppose \( U(x_1, x_2) \) satisfies the transformation law (Eq. (3.73)). Then it is straightforward to check, from Eq. (3.74), that \( U(x_1 + dx_1, x_2) \) satisfies the correct equation. Since \( U \) satisfies a first-order differential equation, this is enough.

Again, the integral around a closed loop, \( C \), is gauge invariant, provided one now takes the trace:

\[ U(x_1, x_1) = Tr e^{i \int_c dx^\mu A_\mu}. \]  (3.76)

Wilson used these objects to construct a discretized version of the usual path integral. Take the lattice to be a simple hypercube, with points \( x^\mu = an^\mu \), where \( n^\mu \) is a vector of integers; \( a \) is called the lattice spacing. At any point, \( x \), one
can construct a simple Wilson line, $U(x)_{\mu\nu}$, known as a plaquette. This is just the product of Wilson lines around a unit square. Letting $n_{\mu}$ denote a unit vector in the $\mu$ direction, we denote the Wilson line $U(x, x + an^{\mu})$ by $U(x)_{\mu}$. These are the basic variables; as they are associated with the lines linking two lattice points, these are called “link variables.” Then the Wilson loops about each plaquette are denoted:

$$U(x)_{\mu\nu} = U(x)_{\mu}U(x + an^{\mu})_{\nu}U(x + an^{\mu} + an^{\nu})_{-\mu}U(x + an^{\nu})_{-\nu}. \quad (3.77)$$

In the non-Abelian case, a trace is understood. For small $a$, in the Abelian case, it is easy to expand $U_{\mu\nu}$ in powers of $a$, and show that:

$$U(x)_{\mu\nu} = e^{ia^{2}F_{\mu\nu}(x)}. \quad (3.78)$$

So we can write an action, which in the limit of small lattice spacing goes over to the Yang–Mills action:

$$S_{\text{wilson}} = \frac{1}{4g^{2}} \sum_{x, \mu, \nu} U(x)_{\mu\nu}. \quad (3.79)$$

In the non-Abelian case, this same expression holds, except with 4 replaced by 2, and a trace over the $U$ matrices.

How might we investigate the question of confinement with this action? Here, Wilson also made a proposal. Consider the amplitude for a process in which a very heavy (infinitely heavy) quark–antiquark pair are produced in the far past, separated by a distance $R$, and allowed to propagate for a long time, $T$, after which they annihilate. In Minkowski space, this amplitude would be given by:

$$\langle f | e^{-iHT} | i \rangle. \quad (3.80)$$

If we transform to Euclidean space, and insert a complete set of states, for each state we have a factor $\exp(-E_{0}T)$. As $T \to \infty$, this becomes $e^{-E_{0}T}$, where $E_{0}$ is the ground state of the system with two infinitely massive quarks, separated by a distance $R$ – what we would naturally identify with the potential of the quark–antiquark system.

In the path integral, this expectation value is precisely the Wilson loop, $U_{P}$, where $P$ is the path from the point of production to the point of annihilation and back. If the quarks only experience a Coulomb force, one expects the Wilson loop to behave as

$$\langle U_{P} \rangle \propto e^{-\alpha T/R} \quad (3.81)$$

for a constant $\alpha$. In other words, the exponential behaves as the perimeter of the loop. If the quarks are confined, with a linear confining force, the exponential behaves as $e^{-bT/R}$, i.e. like the area of the loop. So Wilson proposed to measure the
expectation value of the Wilson loop, and determine whether it obeyed a perimeter or area law.

In strong coupling, it is a simple matter to do the computation in the lattice gauge theory. We are interested in

\[ \int \prod dU(x) e^{-S_{\text{lat}} + i \prod P U} \tag{3.82} \]

We can evaluate this by expanding the exponent in powers of \(1/g^2\). Because

\[ \int dU (x) U\mu = 0 \quad \int dU \mu U\mu U^\dagger \mu = c \tag{3.83} \]

(you can check this easily in the Abelian case), in order to obtain a non-vanishing result, we need to tile the path with plaquettes, as indicated in Fig. 3.5. So the result is exponential in the area,

\[ \langle U_P \rangle = (\text{const}/g^2)^A \tag{3.84} \]

and the force law is

\[ V(R) = \text{const} \frac{g^2}{a^2} R \tag{3.85} \]

This is not a proof of confinement in QCD. First note that this result also holds in the strong-coupling limit of an *Abelian* gauge theory. This is possible because even the pure gauge Abelian lattice theory is an interacting theory. From this we learn that the strong-coupling behavior of a lattice theory can be very different than the weak coupling behavior. In lattice QED, there is a phase transition (a discontinuous change of behavior) between the strong- and weak-coupling phases. In the case of
an asymptotically free theory like QCD, we expect a close correspondence between coupling and lattice size. To describe, say, a proton, we would like to use a lattice on which the spacing $a$ is much smaller than the QCD scale. In this case, the coupling we should use in the lattice theory is small. It is then not at all obvious that the strong-coupling result is applicable. At present, the issue can only be settled by evaluating the lattice path integral numerically. In principle, since the lattice theory reduces space-time to a finite number of points, the required path integral is just an ordinary integral, albeit with a huge number of dimensions. For example, if we have a $10^4$ lattice, with of order $10^4$ links (each $3 \times 3$ matrices), and quarks at each site, it is clear that a straightforward numerical evaluation involves an exponentially large number of operations. In practice, it is necessary to use Monte Carlo (statistical sampling) methods to evaluate the integrals. These techniques are now sufficiently powerful to convincingly demonstrate an area law at weak coupling. The constant in the area law – the coefficient of the linear term in the quark–antiquark potential, is a dimensionful parameter. It must be a renormalization-group invariant. As a result, it must take the form:

$$T = ca^{-2}e^{-\int \frac{dg^2}{8\pi}}.$$  (3.86)

At weak coupling, we know the form of the beta function, so we know how $T$ should behave as we vary the lattice spacing and coupling. Results of numerical studies are in good agreement with these expressions. There has also been great progress in computing the low-lying hadron spectrum and certain weak decay matrix elements.

It is interesting to see how the strong-coupling result arises from a Hamiltonian viewpoint. To simplify the computation, we consider a $U(1)$ gauge theory. In the Hamiltonian approach, the basic dynamical variables are the matrices $U_i$, associated with the spatial directions. There is also $A_0$. As in continuum field theory, we can choose the gauge $A_0 = 0$. In this gauge, in the continuum, the dynamical variables are $A_i$, and their conjugate momenta $E_i$; on the lattice, the conjugate momenta to the $U_i$s are the $E_i$s. The Hamiltonian has the form:

$$H = \sum g^2 \Pi(x)^2 / a + \frac{1}{4g^2} \sum U_{ij}(\vec{x})a^{-1}.$$  (3.87)

The $U_i$s are compact variables, so the $\Pi(x)$s, at each point, are like angular momenta. At strong coupling, this is a system of decoupled rotors. The ground state of the system has vanishing value of these angular momenta.

Now introduce a heavy quark–antiquark pair to the system, separated by a distance $R$ in the $z$ direction. In $A_0 = 0$ gauge, states must be gauge invariant (we will discuss this further when we consider instantons in the next chapter). So a candidate state has the form:

$$|\Psi\rangle = q^\dagger(0)U_z(0, R)\bar{q}^\dagger(R)|0\rangle.$$  (3.88)
3.8 Strong interaction processes at high momentum transfer

QCD has been tested, often with high precision, in a variety of processes at high momentum transfer. It is these processes to which one can apply ordinary perturbation theory. If $Q^2$ is the typical momentum transfer of the process, cross sections are given by a power series in $\alpha_s(q^2)$. The application of perturbation theory, however, is subtle. In accelerators, we observe hadrons; in perturbation theory, we compute the production rate for quarks and gluons. We briefly survey some of these tests in this section. In some ways, the simplest to analyze is $e^+e^-$ annihilation, and we discuss it first. Then we turn to processes involving deep inelastic scattering of leptons by hadrons. Finally, we discuss processes involving hadrons.

3.8.1 $e^+e^-$ Annihilation

Theoretically, perhaps the simplest process to understand is the total cross section in $e^+e^-$ annihilation. At the level of quarks and gluons, the first few diagrams contributing to the production cross section are exhibited in Fig. 3.6. There are, in
perturbation theory, a variety of final states: \( q\bar{q}, q\bar{q} g, q\bar{q} g g, q\bar{q} q\bar{q}, \) and so on. We do not understand, in any detail, how these quarks and gluons materialize as the observed hadrons. But we might imagine that this occurs as in Fig. 3.7. The initial quarks radiate gluons which can in turn radiate quark–antiquark pairs. As the cascade develops, quarks and antiquarks can pair to form mesons; \( qqg \) combinations can form baryons, and so on. In these complex processes (called “hadronization”), we can construct many relativistic invariants, and many will be small, so that perturbation theory cannot be trusted. In a sense this is good; otherwise, we would be able to show that free quarks and gluons were produced in the final states. But if we only ask about the total cross section, each term in the series is a function only of the center of mass energy, \( s \). As a result, if we simply choose \( s \) for the renormalization scale, the cross section is given by a power series in \( \alpha_s(s) \). One way to see this is to note that the cross section is proportional to the imaginary part of the photon vacuum polarization tensor, \( \sigma(s) \propto \text{Im} \, \Pi \). One can calculate \( \Pi \) in Euclidean space, and then analytically continue. In the Euclidean calculation, there are no infrared divergences, so the only scales are \( s \) and the cutoff (or renormalization scale). It is convenient to consider the ratio

\[
R(e^+e^- \rightarrow \text{hadrons}) = \frac{\sigma(e^+e^- \rightarrow \text{hadrons})}{\sigma(e^+e^- \rightarrow \mu^+\mu^-)}. \tag{3.91}
\]

The lowest-order \( (\alpha_s^0) \) contribution can be written down without any work:

\[
R(e^+e^- \rightarrow \text{hadrons}) = 3 \sum Q_j^2 \tag{3.92}
\]

where we have explicitly pulled out a factor of 3 for color, and the sum is over those quark flavors light enough to be produced at energy \( \sqrt{s} \). So, for example, above the charm quark and below the bottom quark threshold, this would give

\[
R(e^+e^- \rightarrow \text{hadrons}) = 10/3. \tag{3.93}
\]
Before comparing with data, we should consider corrections. The cross section has been calculated through order $\alpha_s^3$. Here we quote just the first two orders:

$$ R(e^+e^- \rightarrow \text{hadrons}) = 3 \sum Q_f^2 \left( 1 + \frac{\alpha_s}{\pi} \right). \quad (3.94) $$

This is compared with data in Fig. 3.8.
3 Phenomenology of the Standard Model

Fig. 3.9. Feynman diagrams contributing to $Z$ decay are similar to those in $e^+e^-$ annihilation.

This calculation has other applications. Perhaps the most interesting is the $Z$ width. $Z$ decays to hadrons involve essentially the same Feynman diagrams (Fig. 3.9), except for the different $Z$ couplings to the quarks. Again, this is compared with experiment in Fig. 3.10.

3.8.2 Jets in $e^+e^-$ annihilation

Much more is measured in $e^+e^-$ annihilation than the total cross section, and clearly we would like to extract further predictions from QCD. If we are to be able
to use perturbation theory, it is important that we limit our questions to processes for which all momentum transfers are large. It is also important that perturbation theory fail for some questions. After all, we know that the final states observed in accelerators contain hadrons, not quarks and gluons. If perturbation theory were good for sufficiently precise descriptions of the final state, the theory would simply be wrong.

To understand the issues, let’s briefly recall some features of QED for a process like $e^+e^- \rightarrow \mu^+\mu^-$. At lowest order, one just has the production of the $\mu^+\mu^-$ pair. But in order $\alpha$, one has final states with an additional photon, and loop corrections to the muon lines (also the electron/positron), as indicated in Fig. 3.11. Both the loop corrections and the total cross section for final states with a photon are infrared divergent. In QED, the resolution to this problem is resolution. In an experiment, one cannot detect a photon of arbitrarily low energy. So in comparing the theory with the observed cross section for $\mu^+\mu^-$ (no photon), one must allow for the possibility that a very-low-momentum photon is emitted and not detected. Including some energy resolution, $\Delta E$, the cross sections for each possible final state are finite. If the energy is very large, one also has to keep in mind that experimental detectors cannot resolve photons sufficiently parallel to one or the other of the outgoing muons. The cross section, again, for each type of final state has large logarithms, $\ln(E/m_\mu)$. These are often called “collinear singularities” or “mass singularities.” So one must allow for the finite angular resolution of real experiments. Roughly speaking, then, the radiative corrections for these processes involve

$$\delta \sigma \propto \frac{\alpha}{4\pi} \ln(E/\Delta E) \ln(\Delta \theta). \quad (3.95)$$

As one makes the energy resolution smaller, or the angular resolution smaller, perturbation theory becomes poorer. In QED, it is possible to sum these large, double-logarithmic terms.

In QCD, these same issues arise. Partial cross sections are infrared divergent. One obtains finite results if one includes an energy and angular resolution. But now the coupling is not so small as in QED, and it grows with energy. In other words, if one takes an energy resolution much smaller than the typical energy in the
process, or an angular resolution which is very small, the logarithms which appear in the perturbation expansion signal that the expansion parameter is not $\alpha_s(s)$ but something more like $\alpha_s(\Delta E)$ or $\alpha_s(\Delta \theta s)$. So perturbation theory eventually breaks down.

On the other side, if one does not make $\Delta E$ or $\Delta \theta$ too small, perturbation theory should be valid. Consider, again, $e^+e^-$ annihilation to hadrons. One might imagine the processes which lead to the observed final states involve emission of many gluon and quark–antiquark pairs from the initial outgoing $q\bar{q}$ pair, as in Fig. 3.7. The final emissions will involve energies and momentum transfers of order the masses of pions and other light hadrons, and perturbation theory will not be useful. On the other hand, we can restrict our attention to the kinematic regime where the gluon is emitted at a large angle relative to the quark, and has a substantial energy. There are no large logarithms in this computation, nor in the computation of the $q\bar{q}$ final state. We can give a similar definition for the $q\bar{q}g$ final state. From an experimental point of view, this means that we expect to see jets of particles (or energy-momentum), reasonably collimated, and that we should be able to calculate the cross sections for emission of such jets. These calculations are similar to those of QED. Such jets are observed in $e^+e^-$ annihilation, and their angular distribution agrees well with theoretical expectation. When first observed, these three jet events were described, appropriately, as the “discovery of the gluon.”

3.8.3 Deep inelastic scattering

Deep inelastic scattering was one of the first processes to be studied theoretically in QCD. These are experiments in which a lepton is scattered at high momentum transfer from a nucleus. The lepton can be an electron, a muon, or a neutrino; the exchanged particle can be a $\gamma$, $W^\pm$ or $Z$ (Fig. 3.12). One doesn’t ask about the details
of the final hadronic state, but simply how many leptons are scattered at a given angle. Conceptually, these experiments are much like Rutherford’s experiment which discovered the atomic nucleus. In much the same way, these experiments showed that nucleons contain quarks, of just the charges predicted by the quark model.

This process was attractive because one can analyze it without worrying about issues of defining jets and the like. The total cross section can be related, by unitarity, to a correlation function of two currents: the electromagnetic current, in the case of the photon; the weak currents in the case of the weak gauge bosons. The currents are space-like separated, and this separation becomes small as the momentum transfer, $Q^2$, becomes large. This analysis is described in many textbooks. Instead, we will adopt a different viewpoint, which allows a description of the process which generalizes to other processes involving hadrons at high momentum transfer.

Feynman and Bjorken suggested that we could view the incoming proton as a collection of quarks and gluons, which they collectively referred to as partons. They argued that one could define a probability to find a parton of type $i$ carrying a fraction $x$ of the proton momentum, $f_i(x)$ (and similarly for neutrons). At high momentum transfer, they suggested that the scattering of the virtual photon (or other particle) off the nucleon would actually involve the scattering of this object off one of the partons, the others being “spectators” (Fig. 3.12). In other words, the cross section for deep inelastic scattering would be given by:

$$\sigma(e^-(k) + p(P) \rightarrow e^-(k') + X) = \int d\xi \sum f_i(\xi) \sigma(e^-(k) + q(\xi P) \rightarrow e^-(k') + q_f(p'))$$  \hspace{1cm} (3.96)$$

This assumption may – should – seem surprising. After all, the scattering process is described by the rules of quantum mechanics, and there should be all sorts of complicated interference effects. We will discuss this question below, but for now, suffice it to say that this picture does become correct in QCD for large momentum transfers.

For the case of the virtual photon, the cross section for the parton process can be calculated just as in QED:

$$\frac{d\sigma}{d\hat{t}}(e^-q \rightarrow e^-q) = \frac{2\pi\alpha^2 Q_f^2}{\hat{s}^2} \left[ \frac{\hat{s}^2 + \hat{u}^2}{\hat{t}^2} \right].$$  \hspace{1cm} (3.97)$$

Here $\hat{s}$, $\hat{t}$, $\hat{u}$ are the kinematic invariants of the elementary parton process. For example, if we neglect the mass of the lepton and the incoming nucleon:

$$\hat{s} = 2p \cdot k = 2\xi P \cdot k = \zeta s.$$  \hspace{1cm} (3.98)$$
If the scattered electron momentum is measured, $q$ is known, and we can relate $x$ of the process to measured quantities. From momentum conservation:

$$(\zeta P + q)^2 = 0. \tag{3.99}$$

Or

$$q^2 + 2\zeta P \cdot q = 0. \tag{3.100}$$

Solving for $\zeta$:

$$\zeta = x = -\frac{q^2}{2P \cdot q}. \tag{3.101}$$

It is convenient to introduce another kinematic variable,

$$y = \frac{2P \cdot q}{s} = \frac{2P \cdot q}{2P \cdot k}. \tag{3.102}$$

Then $Q^2 = q^2 = xys$, and we can write a differential cross section:

$$\frac{d^2\sigma}{dx dy}(e^- P \to e^- X) = \left(\sum_f xf_f(x)Q_f^2\right)\frac{2\pi \alpha_s^2 s}{Q^4}[1 + (1 - y)^2]. \tag{3.103}$$

This and related predictions were observed to hold in the first deep inelastic scattering experiments at SLAC, providing the first persuasive experimental evidence for the reality of quarks. Note, in particular, the scaling implied by these relations. For fixed $y$, the cross section is a function only of $x$.

In QCD, these notions need a crucial refinement. The distribution functions are no longer independent of $Q^2$:

$$f_f(x) \to f_f(x, Q^2). \tag{3.104}$$

To understand this, we return to the question: why should a probabilistic model of partons work at all in these very quantum processes? Consider, for example, the Feynman diagrams of Fig. 3.13. Clearly there are complicated interference terms when one squares the amplitude. But it turns out that, in certain gauges, the interference diagrams are suppressed, and the cross section is just given by a square of terms, as in Fig. 3.14. So one gives a probabilistic description of the process, just as Feynman and Bjorken suggested, with the distribution function the result of the sequence of interactions in the figure. These diagrams depend on $Q^2$. One can write integro-differential equations for these functions, the Altareli–Parisi equations. To explain the data, one determines these distribution functions at one value of $Q^2$ from experiment, and evolves them to other values. By now, these have been studied over a broad range of $Q^2$. Some experimental results from the HERA detector at ZEUS (DESY) are shown in Fig. 3.15.
3.8 Strong interaction processes at high momentum transfer

Fig. 3.13. Diagrams contributing to total rate. Diagrams to the right are complex conjugates of corresponding amplitudes on the left. The second term represents a complicated interference.

Fig. 3.14. In suitable gauges, deep inelastic scattering is dominated by absolute squares of amplitudes (interference unimportant).

3.8.4 Other high momentum processes

These ideas have been applied to other processes. The analysis which provides a diagrammatic understanding of deep inelastic scattering shows that the same structure functions are relevant to other high-momentum transfer processes, though care is required in their definitions. Examples include lepton pair production in hadronic collisions (Fig. 3.16) and jet production in hadron collisions. All have been subject to particularly stringent experimental tests.

Suggested reading

There are a number of excellent texts on the Standard Model. *An Introduction to Quantum Field Theory* by Peskin and Schroeder (1995) provides a good introduction both to the theory of weak interactions and to the strong interactions, including deep inelastic scattering, parton distributions and the like. Other excellent texts include the books by Cheng and Li (1984), Donoghue *et al.* (1992), Pokorski (2000), Weinberg (1995), Bailin and Love (1993), Cottingham and Greenwood (1998), and many others. An elegant calculation of the beta function in QCD, which uses
the Wilson loop to determine the potential perturbatively, appears in the lectures of Susskind (1977). These lectures, as well as Wilson’s original paper (1974) and the text of Creutz (1983), provide a good introduction to lattice gauge theory. An important subject which we did not discuss in this chapter is heavy quark physics. This is experimentally important and theoretically accessible. A good introduction is provided in the book by Manohar and Wise (2000).
Exercises

(1) Add to the Lagrangian of Eq. (2.41) a term

$$\delta L = \epsilon \text{Tr} M$$

for small $\epsilon$. Show that, in the presence of $\epsilon$, the expectation values of the $\pi$ fields are fixed, and give a simple physical explanation. Compute the masses of the $\pi$ fields directly from the Lagrangian.

(2) Verify Eqs. (2.48)–(2.56).

(3) Compute the mass of the Higgs field as a function of $\mu$ and $\lambda$. Discuss production of Higgs particles (you do not need to do detailed calculations, but indicate the relevant Feynman graphs and make at least crude estimates of cross sections) in $e^+e^-$, $\mu^+\mu^-$ and $P\bar{P}$ annihilation. Keep in mind that because some of the Yukawa couplings are extremely small, there may be processes generated by loop effects which are bigger than processes which arise at tree level.

(4) Using the formula for the $e^+e^-$ cross section, determine the branching ratio for decay of the $Z$ into hadrons:

$$B(Z \rightarrow \text{hadrons}) = \frac{\Gamma(Z \rightarrow \text{hadrons})}{\Gamma(Z \rightarrow \text{all})}.$$
The Standard Model as an effective field theory

The Standard Model has some remarkable properties. The renormalizable terms respect a variety of symmetries, all of which are observed to hold to a high degree in Nature.

- Baryon number:
  \[ Q \rightarrow e^{i\frac{\alpha}{3}} Q \quad \bar{u} \rightarrow e^{-i\frac{\alpha}{3}} \bar{u} \quad \bar{d} \rightarrow e^{-i\frac{\alpha}{3}} \bar{d}. \]  
  \hfill (4.1)

- Three separate lepton numbers:
  \[ L_f \rightarrow e^{-i\alpha_f} L_f \quad \bar{e}_f \rightarrow e^{i\alpha_f} \bar{e}_f. \]  
  \hfill (4.2)

It is not necessary to impose these symmetries. They are simply consequences of gauge invariance, and the fact that there are only so many renormalizable terms one can write. These symmetries are said to be “accidental,” since they don’t seem to result from any deep underlying principle.

This is already a triumph. As we will see when we consider possible extensions of the Standard Model, this did not have to be. But this success raises the question: why should we impose the requirement of renormalizability?

In the early days of quantum field theory, renormalizability was sometimes presented as a sacred principle. There was a view that field theories were fundamental, and should make sense in and of themselves. Much effort was devoted to understanding whether the theories existed in the limit that the cutoff was taken to infinity.

But there was an alternative paradigm for understanding field theories, provided by Fermi’s original theory of the weak interactions. In this theory, the weak interactions are described by a Lagrangian of the form:

\[ \mathcal{L}_{\text{weak}} = \frac{G_f}{\sqrt{2}} J^\mu J_\mu. \]  
  \hfill (4.3)

Here the currents, \( J^\mu \), are bilinears in the fermions; they include terms like \( Q\sigma^\mu T^a Q^* \). This theory, like the Standard Model, was very successful. It took some
time to actually determine the form of the currents but, for more than forty years, all experiments in weak interactions could be summarized in a Lagrangian of this form. Only as the energies of bosons in $e^+e^-$ experiments approached the $Z$ boson mass were deviations observed.

The four-Fermi theory is non-renormalizable. Taken seriously as a fundamental theory, it predicts violations of unitarity at TeV energy scales. But from the beginning, the theory was viewed as an effective field theory, valid only at low energies. When Fermi first proposed the theory, he assumed that the weak forces were caused by exchange of particles – what we now know as the $W$ and $Z$ bosons.

### 4.0.1 Integrating out the $W$ and $Z$ bosons

Within the Standard Model, we can derive the Fermi theory, and we can also understand the deviations. A traditional approach is to examine the Feynman diagram of Fig. 4.1. This can be understood as a contribution to a scattering amplitude, but it is best understood here as a contribution to the effective action of the quarks and leptons. The currents of the Fermi theory are just the gauge currents which describe the coupling at each vertex. The propagator, in the limit of very-small-momentum transfer, is just a constant. In coordinate space, this corresponds to a space-time $\delta$-function – the interaction is local. The effect is just to give the four-Fermi Lagrangian. One can consider effects of small finite momentum by expanding the propagator in powers of $q^2$. This will give four-Fermi operators with derivatives. These are suppressed by powers of $M_W$ and their effects are very tiny at low energies. Still, in principle, they are there, and in fact the measurement of such terms at energies a significant fraction of $M_Z$ provided the first hints of the existence of the $Z$ boson.

This effective action can also be derived in the path integral approach. Here we literally integrate out the heavy fields, the $W$ and $Z$. In other words, for fixed values of the light fields, which we denote by $\phi$, we do the path integral over $W$ and $Z$,
expressing the result as an effective action for the $\phi$ fields:

$$\int [d\phi] e^{iS_{\text{eff}}} = \int [d\phi] \int [dW_\mu] [dW^*_\mu] \Delta_F p e^{i\int (W_\mu^* (\partial^2 + M^2_\mu) W^\mu + J^\mu W^\mu_\mu + J^{\mu\dagger} W^\mu_{\mu}) d^4 x}.$$  \hspace{1cm} (4.4)

Here, for simplicity, we have omitted the $Z$ particle. We have chosen the Feynman–’t Hooft gauge. The $J^\mu$ and $J^{\mu\dagger}$ are the usual weak currents. They are constructed out of the various light fields, the quarks and leptons, which we have grouped, generically, into the set of fields, $\phi$. Written this way, the path integral is the most basic field theory path integral, and we are familiar with the result:

$$e^{iS_{\text{eff}}} = e^{\int d^4 x d^4 y J^\mu(x) \Delta(x,y) J_{\mu}(y)}.$$  \hspace{1cm} (4.5)

Here $\Delta(x, y)$ denotes the propagator for a scalar of mass $M_W$. In the limit $M \to \infty$, this is just a $\delta$-function (one can compute this, or see this directly from the path integral – if we neglect the derivative terms in the action, the propagator is just a constant in momentum space):

$$\Delta(x, y) = \frac{i}{M^2_W} \delta(x - y).$$  \hspace{1cm} (4.6)

So

$$S_{\text{eff}} = \frac{1}{M^2_W} J^{\mu\dagger} J_{\mu}.$$  \hspace{1cm} (4.7)

The lesson is that, up to the late 1970s, one could view QED + QCD + the Fermi theory as a perfectly acceptable theory of the interactions. The theory would have to be understood, however, as an effective theory, valid only up to an energy scale of order 100 GeV or so. Sufficiently precise experiments would require inclusion of operators of dimension higher than four. The natural scale for these operators would be the weak scale. The Fermi theory is ultraviolet divergent. These divergences would be cut off at scales of order the $W$ boson mass.

### 4.0.2 What might the Standard Model come from?

As successful as the Standard Model is, and despite the fact that it is renormalizable, it is likely that, like the four-Fermi theory, it is the low-energy limit of some underlying, more “fundamental” theory. In the second half of this book, our model for this theory will be string theory. Consistent theories of strings, for reasons which are somewhat mysterious, are theories which describe general relativity and gauge interactions. Unlike field theory, string theory is a finite theory. It does not require a cutoff for its definition. In principle, all physical questions have well-defined answers within the theory. If this is the correct picture for the origin of the laws of Nature at extremely short distances, then the Standard Model is just its low-energy
limit. When we study string theory, we will understand in some detail how such a structure can emerge. For now, the main lesson we should take concerns the requirement of renormalizability: the Standard Model should be viewed as an effective theory, valid up to some energy scale, $\Lambda$. Renormalizability is not a constraint we impose upon the theory; rather, we should include operators of dimension five or higher with coefficients scaled by inverse powers of $\Lambda$. The question of the value of $\Lambda$ is an experimental one. From the success of the Standard Model, as we will see, we know that the cutoff is large. From string theory, we might imagine that $\Lambda \approx M_p = 1.2 \times 10^{18}$ GeV. But, as we will now describe, we have experimental evidence that there is new physics which we must include at scales well below $M_p$. We will also see that there are theoretical reasons to believe that there should be new physics at TeV energy scales.

4.1 Lepton and baryon number violation

We have remarked that at the level of renormalizable operators, baryon and lepton number are conserved in the Standard Model. Viewed as an effective theory, however, we should include higher-dimension operators, with dimensionful couplings. We would expect such operators to arise, as in the case of the four-Fermi theory, as a result of new phenomena and interactions at very high energy scales. The coefficients of these operators would be determined by this dynamics.

There would seem, at first, to be a vast array of possibilities for operators which might be induced in the Standard Model Lagrangian. But we can organize the possible terms in two ways. First, if $M_{bsm}$ is the scale of some new physics, operators of progressively higher dimension are suppressed by progressively larger powers of $M_{bsm}$. Second, the most interesting, and readily detectable, operators are those which violate the symmetry of the renormalizable Lagrangian. This is already familiar in the weak interaction theory. In the Standard Model, the symmetries are precisely baryon and lepton number.

4.1.1 Dimension five: lepton number violation and neutrino mass

To proceed systematically, we should write operators of dimension five, six, and so on. At the level of dimension five, we can write several terms which violate lepton number:

$$\mathcal{L} = \frac{1}{M_{bsm}} \gamma_{f,f'} \phi \phi L_f L'_f + \text{c.c.} \quad (4.8)$$

With non-zero $\phi$, these terms give rise to neutrino masses. This type of mass term is usually called a “Majorana mass.” In nature, these masses are quite small. For
example, if $M_{bsm} = 10^{16}$ GeV, which we will see is a plausible scale, then the neutrino masses would be of order $10^{-3}$ eV. In typical astrophysical and experimental situations, neutrinos are produced with energies of order MeV or larger, so it is difficult to measure these masses by studying the energy-momentum dispersion relation (very sensitive measurements of the end-point spectra beta-decay ($\beta$-decay) set limits of order electronvolts on neutrino mass). More promising are oscillation experiments, in which these operators give rise to transitions between one type of neutrino to another, similar to the phenomenon of $K$ meson oscillations. Roughly speaking, in, say, the $\beta$-decay of a $d$ quark, one produces the neutrino partner of the electron. However, the mass (energy) eigenstate is a linear combination of the three types of neutrino (as we will see, it is typically principally a combination of two). So experiments or observations downstream from the production point will measure processes in which neutrinos produce muons or taus.

In the past few years, persuasive evidence has emerged that the neutrinos do have non-zero masses and mixings. This comes from the study of neutrinos coming from the Sun (the “solar neutrinos”) and neutrinos produced in the upper atmosphere by cosmic rays (which produce pions which subsequently decay to muons and $\nu_\mu$s, whose decays in turn produce electrons, $\nu_\mu$s, and $\nu_e$s). Accelerator and reactor experiments have provided dramatic and beautiful evidence in support of this picture.

Currently, the atmospheric data is best described as a mixing of $\nu_\mu$ and $\nu_\tau$. Because one is examining an oscillation, one does not know the value of the mass, but one determines:

$$\delta m^2_a = 2.4 \times 10^{-3} \text{ eV}^2 \quad \theta_a = 45^\circ \pm 10.$$

Similarly, for the solar neutrinos, which appear to be mainly mixing of $\nu_\mu$ and $\nu_\tau$:

$$\delta m^2_s = 8.2 \times 10^{-5} \text{ eV}^2 \quad \theta_s = 32^\circ \pm 4.$$

It is conceivable that these masses are not described by the Lagrangian of Eq. (4.8). Instead, the masses might be “Dirac,” by which one means that there might be additional degrees of freedom, which by analogy to the $\bar{\nu}$ fields we could label $\bar{\nu}$, with very tiny Yukawa couplings to the normal neutrinos. This would truly represent a breakdown of the Standard Model: even at low energies, we would have been missing basic degrees of freedom. But this does not seem likely. If there are singlet neutrinos, $N$, nothing would prevent them from gaining a “Majorana” mass:

$$L_{\text{Maj}} = MNN.$$

As for the leptons and quarks, there would also be a coupling of $\nu$ to $N$. There would now be a *mass matrix* for the neutrinos, involving both $N$ and $\nu$. For simplicity,
consider the case of just one generation. Then this matrix would have the form:

$$M_\nu = \begin{pmatrix} M & y\nu \\ y\nu & 0 \end{pmatrix}. \quad (4.12)$$

Such a matrix has one large eigenvalue, of order $M$, and one small one, of order $(y^2 v^2)/M$. This provides a natural way to understand the smallness of the neutrino mass; it is referred to as the “seesaw mechanism.” Alternatively, we can think of integrating out the right-handed neutrino, and generating the operator of Eq. (4.8).

It seems more plausible that the observed neutrino mass is Majorana than Dirac, but this is a question that hopefully will be settled in time by experiments searching for neutrinoless double beta-decay, $n + n \rightarrow p + p + e^- + e^-$. If it is Majorana, this suggests that there is another scale in physics, well below the Planck scale. For even if the new Yukawa couplings are of order one, the neutrino mass is of order

$$m_\nu = 10^{-5} \text{eV}(M_p/\Lambda). \quad (4.13)$$

If the Yukawas are small, as are many of the quark Yukawa couplings, the scale can be much larger.

### 4.1.2 Other symmetry-breaking dimension-five operators

There is another class of symmetry-violating dimension-five operators which can appear in the effective Lagrangian. These are electric and magnetic dipole moment operators. For example, the operator

$$L_{\mu e} = \frac{e}{M_{\text{bsm}}} F_{\mu\nu} \bar{\mu} \sigma^{\mu\nu} \mu \quad (4.14)$$

(we are using a four-component notation here) would lead to processes violating muon number conservation, particularly the decay of the muon to an electron and a photon. There are stringent experimental limits on such processes, for example:

$$\text{BR}(\mu \rightarrow e \gamma) < 1.2 \times 10^{-11}. \quad (4.15)$$

Other operators of this type include operators which would generate lepton violating $\tau$ decays, on which the limits are far less stringent.

In the Standard Model, CP is an approximate symmetry. We have explained that three generations of quarks are required to violate CP within the Standard Model. So amplitudes which violate CP must involve all three generations, and are typically highly suppressed. From an effective Lagrangian viewpoint, if we integrate out the $W$ and $Z$ bosons, the operators which violate CP are dimension six, and typically have coefficients suppressed by quark masses and mixing angles, as well as loop factors. As a result, new physics at relatively modest scales has the potential for
dramatic effects. Electric dipole moment operators for quarks or leptons would arise from operators of the form:

\[ \mathcal{L}_d = \frac{e m q}{M_{bsm}^2} \tilde{F}_{\mu \nu} q \sigma^{\mu \nu} q + \text{c.c.}, \quad (4.16) \]

where

\[ \tilde{F}_{\mu \nu} = \frac{1}{2} \epsilon_{\mu \nu \rho \sigma} F^{\rho \sigma} \quad (4.17) \]

The presence of the \( \epsilon \) symbol is the signal of CP violation, as the reader can check. In the non-relativistic limit, this is \( \vec{\sigma} \cdot \vec{E} \). These would lead, for example, to a neutron electric dipole moment of order

\[ d_n = \frac{e}{M_{bsm}}. \quad (4.18) \]

Searches for such dipole moments set limits \( d_n < 10^{-25} \text{ e-cm} \). So, unless there is some source of suppression, \( M_{bsm} \), in CP violating processes, is larger than about \( 10^2 \) TeV.

### 4.1.3 Irrelevant operators and high-precision experiments

There are a number of dimension-five operators on which it is possible to set somewhat less stringent limits, and one case in which there is a possible discrepancy. Corrections to the muon magnetic moment could arise from:

\[ \mathcal{L}_{g-2} = \frac{e}{M_{bsm}} F_{\mu \nu} \bar{\mu} \sigma^{\mu \nu} \mu + \text{c.c.}, \quad (4.19) \]

where \( F_{\mu \nu} \) is the electromagnetic field (in terms of the fundamental \( SU(2) \) and \( U(1) \) fields, one can write similar gauge-invariant combinations which reduce to this at low energies). The muon magnetic moment is measured to extremely high precision, and its Standard Model contribution is calculated with comparable precision. As of this writing, there is a 2.6 \( \sigma \) discrepancy between the two. Whether this reflects new physics or not is uncertain. We will encounter one candidate for this physics when we discuss supersymmetry.

There are other operators on which we can set TeV-scale limits. The success of QCD in describing jet physics allows one to constrain four quark operators which would give rise to a hard component in the scattering amplitude. Such operators might arise, for example, if quarks were composite. Constraints on flavor-changing processes provide tight constraints on a variety of operators. Operators like

\[ \mathcal{L}_{fc} = \frac{1}{M_{bsm}^2} s \sigma^{\mu} d^* s \sigma_{\mu} d^* \quad (4.20) \]
(where we have switched to a two-component notation) would contribute to $K - \bar{K}$ mixing and other processes. This constrains $M_{bsm}$ to be larger than 100 TeV or so. Any new physics at the TeV scale must explain why this operator is so severely suppressed.

### 4.1.4 Dimension-six operators: proton decay

Proceeding to dimension six, we can write numerous terms which violate baryon number, as well as additional lepton-number violating interactions:

$$\mathcal{L}_{bv} = \frac{1}{M_{bsm}^2} Q \sigma^\mu \bar{u}^* L \sigma_\mu \bar{d}^* + \cdots.$$  \hspace{1cm} (4.21)

This can lead to processes such as $p \rightarrow \pi e$. Experiments deep underground set limits of order $10^{33}$ years on this process. Correspondingly, the scale $M_{bsm}$ must be larger than $10^{15}$ GeV.

So viewing the Standard Model as an effective field theory, we see that there are many possible non-renormalizable operators which might appear, but most have scales which are tightly constrained by experiment. One might hope – or despair – that the Standard Model will provide a complete description of nature up to scales many orders of magnitude larger than we can hope to probe in experiment.

But there are a number of reasons to think that the Standard Model is incomplete, and at least one which suggests that it will be significantly modified at scales not far above the weak scale.

### 4.2 Challenges for the Standard Model

The Standard Model is tremendously successful. It describes the physics of strong, weak and electromagnetic interactions with great precision to energies of order 100 GeV, or distances as small as $10^{-17}$ cm. It explains why baryon number and the separate lepton numbers are conserved, with only one assumption: there is no interesting new physics up to some high-energy scale.

On the other hand, the Standard Model cannot be a complete theory. The existence of neutrino mass requires at least additional states (if these masses are Dirac), and more likely some new physics at a high-energy scale which accounts for the Majorana neutrino masses. This scale is probably not larger than $10^{16}$ GeV, well below the Planck scale. The existence of gravity means that there is certainly something missing from the theory. The plethora of parameters – about seventeen, counting those of the minimal Higgs sector – suggests that there is a deeper structure. More directly, features of the big bang cosmology which are now well established cannot be accommodated within the Standard Model.
4.3 The hierarchy problem

4.2.1 A puzzle at the renormalizable level

In the standard model there is a puzzle even at the level of dimension four operators. Consider:

\[ \mathcal{L}_\theta = \theta F \tilde{F}, \]  

(4.22)

where

\[ \tilde{F}_{\mu\nu} = \frac{1}{2} \epsilon_{\mu\nu\rho\sigma} F^{\rho\sigma}. \]  

(4.23)

We usually ignore these because classically they are inconsequential; they are total derivatives and do not modify the equations of motion. In a $U(1)$ theory, for example,

\[ F \tilde{F} = 2 \epsilon^{\mu\nu\rho\sigma} \partial_\mu A_\nu \partial_\rho A_\sigma = 2 \partial_\mu (\epsilon^{\mu\nu\rho\sigma} A_\nu \partial_\rho A_\sigma). \]  

(4.24)

In the next chapter, we will see that this has a non-Abelian generalization, but that despite being a total divergence, these terms have real effects at the quantum level. In QCD, they turn out to be highly constrained. From the limits on the neutron electric dipole moment, one can show that $\theta < 10^{-9}$. This is the first real puzzle we have encountered. Why such a small dimensionless number? Answering this question, as we will see, may point to new physics.

4.3 The hierarchy problem

The second very puzzling feature is the Higgs field. As of this writing, the Higgs field is the one piece of the Standard Model which has not been seen. Indeed, the structure we have postulated, a single Higgs doublet with a particular potential, might be viewed as somewhat artificial. We could have included several doublets, or perhaps tried to explain the breaking of the gauge symmetry through some more complicated dynamics. But there is a more serious question associated with fundamental scalar fields, raised long ago by Ken Wilson. This problem is often referred to as the hierarchy problem.

Consider, first, the one-loop corrections to the electron mass in QED. These are logarithmically divergent. In other words,

\[ \delta m = am_0 \frac{\alpha}{4\pi} \ln(\Lambda). \]  

(4.25)

We can understand this result in simple terms. In the limit $m_0 \to 0$, the theory has an additional symmetry, a chiral symmetry, under which $e$ and $\bar{e}$ transform by independent phases. This symmetry forbids a mass term, so the result must be linear in the (bare) mass. So, on dimensional grounds, any divergence is at most logarithmic. This actually resolves a puzzle of classical electrodynamics. Lorentz modeled the electron as a uniformly charged sphere of radius $a$. As $a \to 0$, the
electrostatic energy diverges. In modern terms, we would say that we know $a$ is smaller than $10^{-17}$ cm, corresponding to a self-energy far larger than the electron mass itself. But we see that in the quantum theory, the cutoff occurs at a scale of order the electron mass, and there is no large self-energy correction.

But for scalars, there is no such symmetry, and corrections to masses are quadratically divergent. One can see this quickly for the Higgs self-coupling, which gives rise to a mass correction of the form:

$$\delta m^2 = \lambda^2 \int \frac{d^4k}{(2\pi)^4(k^2 - m^2)}.$$  \hspace{1cm} (4.26)

If we view the Standard Model as an effective field theory, this integral should be cut off at a scale where new physics enters. We have argued that this might occur at, say, $10^{14}$ GeV. But in this case the correction to the Higgs mass is gigantic compared to the Higgs mass itself.

### 4.4 Dark matter and dark energy

In a sense, our analysis seems backwards. We began with a discussion of dimension five and six operators, operators which are irrelevant, and then turned our attention to the Higgs mass, a dimension two, relevant operator. We still have not considered the most relevant operator of all, the unit operator, with dimension zero.

In recent years, astronomers and astrophysicists have presented persuasive evidence that the energy density of the universe is largely in some unfamiliar form; about 30% some non-baryonic pressureless matter (the dark matter) and about 60% in some form with negative pressure (the dark energy). The latter might be a cosmological constant (of which more later). The former could well be some new type of weakly interacting particle. Dark matter would indicate the existence of additional, possibly quite light degrees of freedom in nature. The dark energy is totally mysterious. It could be the energy of the vacuum, the cosmological constant. If so, it is even more puzzling than the hierarchy problem we described before. In field theory this energy is quartically divergent; it is the first divergence one encounters in any quantum field theory textbook. At one loop, it is given by an expression of the form:

$$\Lambda = \sum_i (-1)^F \int \frac{d^3k}{(2\pi)^3} \frac{1}{2\sqrt{k^2 + m_i^2}}$$ \hspace{1cm} (4.27)

where the sum is over all particle species (including spins). This is just the sum of the zero-point energies of the oscillators of each momentum. If one cuts this off, again at $10^{14}$ GeV, one gets a result of order

$$\Lambda = 10^{54} \text{ GeV}^4.$$ \hspace{1cm} (4.28)
The measured value of the dark-energy density, by contrast, is

\[ \Lambda = 10^{-47} \text{ GeV}^4. \quad (4.29) \]

This wide discrepancy is probably one of the most troubling problems facing fundamental physics today.

### 4.5 Summary: successes and limitations of the Standard Model

Overall, we face a tension between the striking successes of the Standard Model and its limitations. On the one hand, the model successfully accounts for almost all of the phenomena observed in accelerators. On the other, it fails to account for some of the most basic phenomena of the universe: dark matter, dark energy, and the existence of gravity itself. As a theoretical structure, it also explains successfully what might be viewed as mysterious conservation laws: baryon and separate lepton numbers. But it has seventeen parameters – sixteen of which are pure numbers, with values which range “all over the map.” The rest of this book explores possible solutions of these puzzles, and their implications for particle physics, astrophysics and cosmology.

**Suggested reading**

There are a number of excellent texts on the Standard Model. *An Introduction to Quantum Field Theory* by Peskin and Schroeder (1995) provides a good introduction both to the theory of weak interactions and to the strong interactions, including deep inelastic scattering, parton distributions and the like. Other excellent texts include the books by Cheng and Li (1984), Donoghue *et al.* (1992), Pokorski (2000), Bailin and Love (1993), and many others.
While perturbation theory is a powerful and useful tool in understanding field theories, for our exploration of physics beyond the Standard Model, an understanding of non-perturbative physics will be crucial. There are many reasons for this.

(1) One of the great mysteries of the Standard Model is non-perturbative in nature: the smallness of the $\theta$ parameter.

(2) Strongly interacting field theories will figure in many proposals to understand mysteries of the Standard Model.

(3) The interesting dynamical properties of supersymmetric theories, both those directly related to possible models of nature and those which provide insights into broad physics issues, are non-perturbative in nature.

(4) If string theory describes nature, non-perturbative effects are necessarily critical.

We have introduced lattice gauge theory, which is perhaps our only tool for doing systematic calculations in strongly coupled theories. But, as a tool, its value is quite limited. Only a small number of calculations are tractable, in practice, and the difficult numerical challenges sometimes obscure the underlying physics. Fortunately, there is a surprising amount that one can learn from symmetry considerations, semiclassical arguments and from our experimental knowledge of one strongly coupled theory, QCD. In each of these, an important role is played by the phenomena known as anomalies, and related to these a set of semiclassical field configurations known as instantons.

Usually, the term anomaly is used to refer to the quantum-mechanical violation of a symmetry which is valid classically. Instantons are finite-action solutions of the Euclidean equations of motion, typically associated with tunneling phenomena. Anomalies are crucial to understanding the decay of the $\pi^0$ in QCD. Anomalies and instantons account for the absence of a ninth light pseudoscalar meson in the hadron spectrum. Within the weak-interaction theory, anomalies and instantons lead to violation of baryon and lepton number; these effects are unimaginably
tiny at the current time, but were important in the early universe. Absence of anomalies in gauge currents is important to the consistency of theoretical structures, including both field theories and string theories. The cancellation of anomalies within the Standard Model itself is quite non-trivial. Similar constraints on possible extensions of the Standard Model will be very important. In the previous chapter, we mentioned the $\theta$ parameter of QCD. This term seems innocuous, but, due to anomalies and instantons, its potential effects are real. Because the $\theta$ term violates CP, they are also dramatic. The problem of the smallness of the $\theta$ parameter – the strong CP problem – strongly suggests new phenomena beyond the Standard Model, and this will be a recurring theme in this book. In this chapter, we explain how anomalies arise and some of the roles which they play. The discussion is meant to provide the reader with a good working knowledge of these subjects, but it is not encyclopedic. A guide to texts and reviews on the subject appears at the end of the chapter.

5.1 The chiral anomaly

Before considering real QCD, consider a non-Abelian gauge theory theory, with only a single flavor of quark. Before making any field redefinitions, the Lagrangian takes the form:

$$L = -\frac{1}{4g^2} F^2_{\mu\nu} + \bar{q} D^\mu \sigma_\mu \bar{q}^* + q D^\mu \sigma_\mu q^* + m\bar{q}q + m^*\bar{q}^* q^*. \quad (5.1)$$

The Lagrangian, here, is written in terms of two-component fermions (see Appendix A). The fermion mass need not be real,

$$m = |m| e^{i\theta}. \quad (5.2)$$

In this chapter, it will sometimes be convenient to work with four component fermions, and it is valuable to make contact with this language in any case. In terms of these, the mass term is:

$$L_m = \text{Re}(m) \bar{q}q + \text{Im}(m) \bar{q}\gamma_5 q. \quad (5.3)$$

In order to bring the mass term to the conventional form, with no $\gamma_5$s, one could try to redefine the fermions; switching back to the two-component notation:

$$q \to e^{-i\theta/2} q \quad \bar{q} \to e^{-i\theta/2} \bar{q}. \quad (5.4)$$

But, in field theory, transformations of this kind are potentially fraught with difficulties because of the infinite number of degrees of freedom.
A simple calculation uncovers one of the simplest manifestations of an anomaly. Suppose, first, that \( m \) is very large, \( m \to M \). In that case we want to integrate out the quarks and obtain a low-energy effective theory. To do this, we study the path integral:

\[
Z = \int [dA_\mu] \int [dq][d\bar{q}] e^{iS} \quad (5.5)
\]

Suppose \( M = e^{i\theta} |M| \). In order to make \( m \) real, we can again make the transformations: \( q \to q e^{-i\theta/2}; \bar{q} \to \bar{q} e^{-i\theta/2} \) (in four-component language, this is \( q \to e^{-i\theta/2}\gamma_5 q \)). The result of integrating out the quark, i.e. of performing the path integral over \( q \) and \( \bar{q} \), can be written in the form:

\[
Z = \int [dA_\mu] \int e^{iS_{\text{eff}}}. \quad (5.6)
\]

Here \( S_{\text{eff}} \) is the effective action which describes the interactions of gluons at scales well below \( M \).

Because the field redefinition which eliminates \( \theta \) is just a change of variables in the path integral, one might expect that there can be no \( \theta \)-dependence in the effective action. But this is not the case. To see this, suppose that \( \theta \) is small, and instead of making the field redefinition, treat the \( \theta \) term as a small perturbation by expanding the exponential. Now consider a term in the effective action with two external gauge bosons. This is obtained from the Feynman diagram in Fig. 5.1. The corresponding term in the action is given by

\[
\delta \mathcal{L}_{\text{eff}} = -i \frac{\theta}{2} g^2 M \text{Tr}(T^a T^b) \int \frac{d^4 p}{(2\pi)^4} \text{Tr} \gamma_5 \frac{1}{p + \not{k}_1 - M} \frac{1}{p - \not{\phi}_1 - M} \frac{1}{p - \not{\phi}_2 - \not{k}_2 - M}. \quad (5.7)
\]

Here, the \( k_i \)s are the momenta of the two photons, while the \( \epsilon \)s are their polarizations and \( a \) and \( b \) are the color indices of the gluons. Introducing Feynman parameters
and shifting the \( p \) integral, gives:

\[
\delta L_{\text{eff}} = -i \theta g^2 M \text{Tr}(T^a T^b) \int d\alpha_1 d\alpha_2 \int \frac{d^4 p}{(2\pi)^4} \text{Tr} \gamma_5 (p - \alpha_1 k_1 + \alpha_2 k_2 + M) \nonumber \\
\times \frac{(p - \alpha_1 k_1 + \alpha_2 k_2 + M) \nonumber}{(p^2 - M^2 + O(k_i^2))^3}. \tag{5.8}
\]

For small \( k_i \), we can neglect the \( k \)-dependence of the denominator. The trace in the numerator is easy to evaluate, since we can drop terms linear in \( p \). This gives, after performing the integrals over the \( \alpha \)s,

\[
\delta L_{\text{eff}} = g^2 M^2 \theta \text{Tr}(T^a T^b) \epsilon_{\mu \nu \rho \sigma} k_1^\mu k_2^\nu \epsilon_1^\rho \epsilon_2^\sigma \int \frac{d^4 p}{(2\pi)^4} \frac{1}{(p^2 - M^2)3}. \tag{5.9}
\]

This corresponds to a term in the effective action, after doing the integral over \( p \) and including a combinatoric factor of two from the different ways to contract the gauge bosons:

\[
\delta L_{\text{eff}} = \frac{1}{32\pi^2} \theta \text{Tr}(F \tilde{F}). \tag{5.10}
\]

Now why does this happen? At the level of the path integral, the transformation would seem to be a simple change of variables, and it is hard to see why this should have any effect. On the other hand, if one examines the diagram of Fig. 5.1, one sees that it contains terms which are linearly divergent, and thus it should be regulated. A simple way to regulate the diagram is to introduce a Pauli–Villars regulator, which means that one subtracts off a corresponding amplitude with some very large mass \( \Lambda \). However, our expression above is independent of \( \Lambda \). So the \( \theta \)-dependence from the regulator fields cancels that of Eq. (5.10). This sort of behavior is characteristic of an anomaly.

Consider now the case that \( m \ll \Lambda_{\text{QCD}} \). In this case, we shouldn’t integrate out the quarks, but we still need to take into account the regulator diagrams. So if we redefine the fields so that the quark mass is real (\( \gamma_5 \)-free, in the four-component description), the low-energy theory contains light quarks and the \( \theta \) term of Eq. (5.10).

We can describe this in a fashion which indicates why this is referred to as an anomaly. For small \( m \), the classical theory has an approximate symmetry under which

\[
q \rightarrow e^{i\alpha} q \quad \bar{q} \rightarrow e^{i\alpha} \bar{q} \tag{5.11}
\]

(in four-component language, \( q \rightarrow e^{i\alpha\gamma_5} q \)). In particular, we can define a current:

\[
j_5^\mu = \bar{q} \gamma_5 \gamma_\mu q \tag{5.12}
\]
and, classically,
\[ \partial_{\mu} j^\mu_5 = m\bar{q}\gamma_5 q. \]  \hspace{1cm} (5.13)

Under a transformation by an infinitesimal angle \( \alpha \) one would expect
\[ \delta L = \alpha \partial_{\mu} j^\mu_5 = m\alpha\bar{q}\gamma_5 q. \]  \hspace{1cm} (5.14)

But the divergence of the current contains another, \( m \)-independent term:
\[ \partial_{\mu} j^\mu_5 = m\bar{q}\gamma_5 q + \frac{1}{32\pi^2} F\tilde{F}. \]  \hspace{1cm} (5.15)

The first term just follows from the equations of motion. To see that the second term is present, we can study a three-point function involving the current and two gauge bosons, ignoring the quark mass:
\[ \Gamma^{AAj}_1 = T\langle \partial_{\mu} j^5_\mu A_\rho A_\sigma \rangle. \]  \hspace{1cm} (5.16)

This is essentially the calculation we encountered above. Again, the diagram is linearly divergent and requires regularization. Let’s first consider the graph without the regulator mass. The graph of Fig. 5.1 is actually two graphs, because we must include the interchange of the two external gluons. The combination is easily seen to vanish, by the sorts of manipulations one usually uses to prove Ward identities:

\[ \frac{g^2}{(2\pi)^4} \int d^4p Tr q\gamma_5 \frac{1}{p + k_1} \frac{1}{\rho} \frac{1}{\rho - k_2} + (1 \leftrightarrow 2). \]  \hspace{1cm} (5.17)

Writing
\[ q\gamma_5 = -\gamma_5 (k_1 + \rho) - (\rho - k_2)\gamma_5 \]  \hspace{1cm} (5.18)

and using the cyclic property of the trace, one can cancel a propagator in each term. This leaves:
\[ \int d^4p Tr \left( -\gamma_5 \frac{1}{\rho} \frac{1}{\rho - k_2} - \gamma_5 \frac{1}{\rho + k_1} \frac{1}{\rho} \frac{1}{\rho - k_2} + (1 \leftrightarrow 2) \right). \]  \hspace{1cm} (5.19)

Now shifting \( p \to p + k_2 \) in the first term, and \( p \to p + k_1 \) in the second, one finds a pairwise cancellation.

These manipulations, however, are not reliable. In particular, in a highly divergent expression, the shifts do not necessarily leave the result unchanged. With a Pauli–Villars regulator, the integrals are convergent and the shifts are reliable, but the regulator diagram is non-vanishing, and gives the anomaly equation above. One can see this by a direct computation, or relate it to our previous calculation, including the masses for the quarks, and noting that \( q\gamma_5 \), in the diagrams with massive quarks, can be replaced by \( M\gamma_5 \).
This anomaly can be derived in a number of other ways. One can define, for example, the current by “point splitting,”

\[ j^\mu_5 = \bar{q}(x + i \epsilon)e^{i \int_0^{\epsilon + i} dx^\alpha A_\alpha} q(x). \tag{5.20} \]

Because operators in quantum field theory are singular at short distances, the Wilson line makes a finite contribution. Expanding the exponential carefully, one recovers the same expression for the current. We will do this shortly in two dimensions, leaving the four-dimensional case for the problems. A beautiful derivation, closely related to that we have performed above, is due to Fujikawa. Here one considers the anomaly as arising from a lack of invariance of the path integral measure. One carefully evaluates the Jacobian associated with the change of variables \( q \rightarrow q(1 + i \gamma_5 \alpha) \), and shows that it yields the same result. We will do a calculation along these lines in a two-dimensional model shortly, leaving the four-dimensional case for the problems.

### 5.1.1 Applications of the anomaly in four dimensions

The anomaly has a number of important consequences for real physics.

- The \( \pi^0 \) decay: the divergence of the axial isospin current,

\[ (j^3_5)^\mu = \bar{u} \gamma_5 \gamma^\mu \bar{u} - \bar{d} \gamma_5 \gamma^\mu d, \tag{5.21} \]

has an anomaly due to electromagnetism. This gives rise to a coupling of the \( \pi^0 \) to two photons, and the correct computation of the lifetime was one of the early triumphs of the theory of quarks with color. The computation of the \( \pi^0 \) decay rate appears in the exercises.

- Anomalies in gauge currents signal an inconsistency in a theory. They mean that the gauge invariance, which is crucial to the whole structure of gauge theories (e.g., to the fact that they are simultaneously unitary and Lorentz-invariant) is lost. The absence of gauge anomalies is one of the striking ingredients of the Standard Model, and it is also crucial in extensions such as string theory.

- The anomaly, as we have indicated, accounts for the absence of a ninth axial Goldstone boson in the QCD spectrum.

### 5.1.2 Return to QCD

What we have just learned is that, if in our simple model above, we require that the quark masses are real, we must allow for the possible appearance, in the Lagrangian of the standard model, of the \( \theta \) terms of Eq. (5.10). In the weak interactions, this term does not have physical consequences. At the level of the renormalizable terms, we have seen that the theory respects separate \( B \) and \( L \) symmetries; \( B \), for example,
is anomalous. So if we simply redefine the quark fields by a $B$ transformation, we can remove $\theta$ from the Lagrangian.

For the $\theta$ angles of QCD and QED, we have no such symmetry. In the case of QED, we do not really have a non-perturbative definition of the theory, and the effects of $\theta$ are hard to assess, but one might expect that, embedded in any consistent structure (like a grand unified theory (GUT) or String Theory) they will be very small, possibly zero. As we saw, $F \tilde{F}$ is a total divergence. The right-hand side of Eq. (4.24) is not gauge invariant, however, so one might imagine that it could be important. But as long as $A$ falls off at least as fast as $1/r$ ($F$ falls faster than $1/r^2$), the surface term behaves as $1/r^4$, and so vanishes.

In the case of non-Abelian gauge theories, the situation is more subtle. It is again true that $F \tilde{F}$ can be written as a total divergence:

$$F \tilde{F} = \partial_\mu K_\mu \quad K_\mu = \epsilon_{\mu \nu \rho \sigma} \left( A^a_\nu F^a_{\rho \sigma} - \frac{2}{3} f^{abc} A^a_\nu A^b_\rho A^c_\sigma \right). \quad (5.22)$$

But now the statement that $F$ falls faster than $1/r^2$ does not permit an equally strong statement about $A$. We will see shortly that there are finite-action classical solutions for which $F \sim 1/r^4$, but $A \to 1/r$, so that the surface term cannot be neglected. These solutions are called instantons. It is because of this that $\theta$ can have real physical effects.

### 5.2 A two-dimensional detour

There are many questions in four dimensions which we cannot answer except with numerical lattice calculation. These include the problem of dimensional transmutation and the effects of the anomaly on the hadron spectrum. There are a class of models in two dimensions which are asymptotically free and in which one can study these questions in a controlled approximation. Two dimensions are often a poor analog for four, but for some of the issues we are facing here, the parallels are extremely close. In these two-dimensional examples, the physics is more manageable, but still rich. In four dimensions, the calculations are qualitatively similar; they are only more difficult because the Dirac algebra and the various integrals are more involved.

#### 5.2.1 The anomaly in two dimensions

First we investigate the anomaly in the quantum electrodynamics of a massless fermion in two dimensions; this will be an important ingredient in the full analysis. The point-splitting method is particularly convenient here. Just as in four
dimensions, we write:

\[ j_5^\mu = \bar{\psi}(x + \epsilon)e^{i j_5^{\mu+\epsilon}} A_\rho dx^\rho \gamma^\mu \gamma^5 \psi(x). \]  

(5.23)

Naively, one can set \( \epsilon = 0 \) and the divergence vanishes by the equations of motion. But in quantum field theory, products of operators become singular as the operators come very close together. For very small \( \epsilon \), we can pick up the leading singularity in the product of \( \psi(x + \epsilon)\psi \) by using the operator product expansion (OPE). The OPE states that the product of two operators at short distances can be written as a series of local operators of progressively higher dimension, with less and less singular coefficients. For our case, this means:

\[ \bar{\psi}(x + \epsilon)\gamma^\mu \gamma^5 \psi(x) = \sum \frac{c_n}{\epsilon^{1-n}} \mathcal{O}_n(x) \]  

(5.24)

where \( \mathcal{O}_n \) is an operator of dimension \( n \). The leading term comes from the unit operator. To evaluate its coefficient, we can take the vacuum expectation value of both sides of this equation. On the left-hand side, this is just the propagator.

It is not hard to work out the fermion propagator in coordinate space in two dimensions. For simplicity, we work with space-like separations, so we can Wick-rotate to Euclidean space. Start with the scalar propagator:

\[ \langle \phi(x)\phi(0) \rangle = \int \frac{d^2 p}{(2\pi)^2} \frac{1}{k^2} e^{-ip \cdot x} = \frac{1}{2\pi} \ln(|x|\mu), \]  

(5.25)

where \( \mu \) is an infrared cutoff. (When we come to string theory, this propagator, with its infrared sensitivity, will play a crucial role.) Correspondingly, the fermion propagator is:

\[ \langle \bar{\psi}(x + \epsilon)\psi(x) \rangle = \bar{\psi}(\phi(x)\phi(0)) = \frac{1}{2\pi} \frac{g'}{\epsilon^2}. \]  

(5.26)

Expanding the factor in the exponential to order \( \epsilon \) gives

\[ \partial_\mu j_5^\mu = \text{naive piece} + \frac{i}{2\pi} \partial_\mu \epsilon_\rho A_\rho tr \frac{g'}{\epsilon^2} \gamma^\mu \gamma^5. \]  

(5.27)

Taking the trace gives \( \epsilon_{\mu\nu} \epsilon^\nu \); averaging \( \epsilon \) over angles (\( \langle \epsilon_{\mu\nu} \epsilon^\nu \rangle = \frac{1}{2} \eta_{\mu\nu} \epsilon^2 \)), yields

\[ \partial_\mu j_5^\mu = \frac{1}{2\pi} \epsilon_{\mu\nu} F^{\mu\nu}. \]  

(5.28)

This is parallel to the situation in four dimensions. The divergence of the current is itself a total derivative:

\[ \partial_\mu j_5^\mu = \frac{1}{2\pi} \epsilon_{\mu\nu} \partial^\mu A^\nu. \]  

(5.29)
So it is possible to define a new current which is conserved:

\[ J^\mu = j^\mu_s - \frac{1}{2\pi} \epsilon^\mu_v A^v \]  

(5.30)

However, just as in the four-dimensional case, this current is not gauge invariant. There is a familiar field configuration for which \( A \) does not fall off at infinity: the field of a point charge. If one has charges, \( \pm \theta \) at infinity, they give rise to a constant electric field, \( F_{0i} = \pm e\theta \). So \( \theta \) has a very simple interpretation in this theory.

It is easy to see that physics is periodic in \( \theta \). For \( \theta > q \), it is energetically favorable to produce a pair of charges from the vacuum which shield the charge at \( \infty \).

### 5.2.2 Path integral computation of the anomaly

One can also do this calculation in the path integral, following Fujikawa. The redefinition of the fields which eliminates the phase in the fermion mass matrix, from this point of view, is just a change of variables. The question is: what is the Jacobian. The Euclidean path integral is defined by expanding the fields:

\[ \psi(x) = \sum a_n \psi_n(x) \]  

(5.31)

where

\[ \mathcal{D}\psi_n(x) = \lambda_n \psi_n(x) \]  

(5.32)

and the measure is:

\[ \int \Pi da_n d\psi^*_n. \]  

(5.33)

Here, for normalized functions \( \psi_n \),

\[ a_n = \int d^2x \psi^*_n(x)\psi(x). \]  

(5.34)

So, under an infinitesimal \( \gamma_5 \) transformation, we have:

\[ \delta \psi = i \theta \gamma_5 \psi \]  

(5.35)

\[ \delta a_n = i \theta \int d^2x \psi_n(x)\gamma_5 \psi_m(x)a_m. \]  

(5.36)

The required Jacobian is then:

\[ \det \left( \delta_{nn'} + i \theta \int \bar{\psi}_{n'} \gamma_5 \psi_n \right). \]  

(5.37)

To evaluate this determinant, we write \( \det(M) = e^{\text{Tr} \log M} \). To linear order in \( \theta \), we need to evaluate:

\[ \text{Tr} i \theta \gamma_5. \]  

(5.38)
This trace must be regularized. A simple procedure is to replace the determinant by:

\[ \text{Tr} \, i \theta \gamma_5 e^{-(\lambda_n^2 / M^2)} . \]  

At the end of the calculation, we should take \( M \to \infty \). We can replace \( \lambda_n^2 \) by

\[ \mathcal{D} \mathcal{D} = D^2 + \frac{1}{2} \sigma_{\mu \nu} F^{\mu \nu} . \]

Expanding in powers of \( F^{\mu \nu} \), it is only necessary to work to first order (in the analogous calculation in four dimensions, it is necessary to work to second order). In other words, we expand the exponent to first order in \( F^{\mu \nu} \) and replace \( D^2 \to p^2 \). The required trace is:

\[ i \theta \int \frac{d^2 p}{p^2} \text{Tr}(\gamma_5 \sigma_{\mu \nu}) \frac{F^{\mu \nu}}{M} e^{-\frac{p^2}{M^2}} . \]

The trace here now just refers to the trace over the Dirac indices. The momentum integral is elementary, and we obtain

\[ \int \Pi d a_n d a_n^* \to \int \Pi d a_n d a_n^* e^{i \frac{\theta}{\pi} \int d^2 x \epsilon_{\mu \nu} F^{\mu \nu}} . \]

Interpreting the divergence of the current as the variation of the effective Lagrangian, we see that we have recovered the anomaly equation. The anomaly in four and other dimensions can also be calculated in this way. The exercises at the end of the chapter provide more details of these computations.

### 5.2.3 The CP\(^N\) model: an asymptotically free theory

The model we have considered so far is not quite like QCD in at least two ways. First, there are no instantons; second, the coupling \( e \) is dimensionful. We can obtain a theory closer to QCD by considering a class of theories with dimensionless couplings, the non-linear \( \sigma \)-models. These are models whose fields are the coordinates of some smooth manifold. They can be, for example, the coordinates of an \( n \)-dimensional sphere. An interesting case is the CP\(^N\) model; here the CP stands for “complex projective” space. This space is described by a set of coordinates, \( z_i, \ i = 1, \ldots, N + 1 \), where \( z_i \) is identified with \( \alpha z_i \), where \( \alpha \) is any complex constant. Alternatively, we can define the space through the constraint:

\[ \sum_i |z_i|^2 = 1 ; \]  

where the point \( z_i \) is equivalent to \( e^{i \alpha} z_i \). In the field theory, the \( z_i \)s become two-dimensional fields, \( z_i(x) \). To implement the first of the constraints, we can add to the action a Lagrange multiplier field, \( \lambda(x) \). For the second, we observe that
the identification of points in the “target space,” \( \mathbb{CP}^N \), must hold at every point in ordinary space-time, so this is a \( U(1) \) gauge symmetry. So introducing a gauge field, \( A_\mu \), and the corresponding covariant derivative, we want to study the Lagrangian:

\[
\mathcal{L} = \frac{1}{g^2} [\sum |D_\mu z_i|^2 - \lambda(x)(|z_i|^2 - 1)].
\] (5.44)

Note that there is no kinetic term for \( A_\mu \), so we can simply eliminate it from the action using its equations of motion. This yields

\[
\mathcal{L} = \frac{1}{g^2} [\sum |\partial_\mu z_j|^2 + |z_j^* \partial_\mu z_j|^2].
\] (5.45)

It is easier to proceed, however, keeping \( A_\mu \) in the action. In this case, the action is quadratic in \( z \), and we can integrate out the \( z \) fields:

\[
Z = \int [dA][d\lambda][dz_j] \exp[-S] = \int [dA][d\lambda] \exp \left[ -\int d^2x \Gamma_{\text{eff}}[A, \lambda] \right]
\]

\[
= \int [dA][d\lambda] \exp \left[ -N \text{tr} \log(-D^2 - \lambda) - \frac{1}{g^2} \int d^2x \lambda \right].
\] (5.46)

### 5.2.4 The large-\( N \) limit

By itself, the result of Eq. (5.46) is still rather complicated. The fields \( A_\mu \) and \( \lambda \) have non-linear and non-local interactions. Things become much simpler if one takes the “large \( N \) limit,” \( N \to \infty \) with \( g^2 N \) fixed. In this case, the interactions of \( \lambda \) and \( A_\mu \) are suppressed by powers of \( N \). For large \( N \), the path integral is dominated by a single field configuration, which solves

\[
\frac{\delta \Gamma_{\text{eff}}}{\delta \lambda} = 0
\] (5.47)

or, setting the gauge field to zero,

\[
N \int \frac{d^2k}{(2\pi)^2} \frac{1}{k^2 + \lambda} = \frac{1}{g^2}.
\] (5.48)

The integral on the left-hand side is ultraviolet divergent. We will simply cut it off at scale \( M \). This gives:

\[
\lambda = m^2 = M \exp \left[ -\frac{2\pi}{g^2 N} \right].
\] (5.49)

Here, a theory which is scale invariant, classically, exhibits a mass gap. This is the phenomenon of dimensional transmutation. These masses are related in a renormalization-group-invariant fashion to the cutoff. So the theory is quite analogous to QCD. We can read off the leading term in the beta (\( \beta \)-)function from the
familiar formula:

\[ m = Me^{-\int \frac{dg}{\beta(g)}} \]  

(5.50)

so, with

\[ \beta(g) = -\frac{1}{2\pi}g^3 b_0 \]  

(5.51)

we have \( b_0 = 1 \).

But most important for our purposes, it is interesting to explore the question of \( \theta \)-dependence. Just as in \( 1 + 1 \)-dimensional electrodynamics, we can introduce a \( \theta \) term:

\[ S_\theta = \frac{\theta}{2\pi} \int d^2 x \epsilon_{\mu\nu} F^{\mu\nu}. \]  

(5.52)

Here \( F^{\mu\nu} \) can be expressed in terms of the fundamental fields \( z_j \). As usual, this is the integral of a total divergence. But precisely as in the case of \( 1 + 1 \)-dimensional electrodynamics we discussed above, this term is physically important. In perturbation theory in the model, this is not entirely obvious. But using our reorganization of the theory at large \( N \), it is. The lowest-order action for \( A_\mu \) is trivial, but at one loop (order \( 1/N \)), one generates a kinetic term for \( A \) through the vacuum polarization loop:

\[ \mathcal{L}_{\text{kin}} = \frac{N}{2\pi m^2} F^{\mu\nu}_\mu F^{\mu\nu}_\nu. \]  

(5.53)

At this order, then, the effective theory consists of the gauge field, with coupling \( e^2 = 2\pi m^2/N \), and some coupling to a set of charged massive fields, \( z \). As we have already argued, \( \theta \) corresponds to a non-zero background electric field due to charges at infinity, and the theory clearly has non-trivial \( \theta \)-dependence.

To this model one can add massless fermions. In this case, one has an anomalous \( U(1) \) symmetry, as in QCD. There is then no \( \theta \)-dependence; by redefining the fermions, \( \psi \rightarrow e^{i\alpha\theta} \psi \), one can eliminate \( \theta \). In this model, the absence of \( \theta \)-dependence can be understood more physically: \( \theta \) represents a charge at \( \infty \), and it is possible to shield any such charge with massless fermions. But there is non-trivial breaking of the \( U(1) \) symmetry. At low energies, one has now a theory with a fermion coupled to a dynamical \( U(1) \) gauge field. The breaking of the associated \( U(1) \) in such a theory is a well-studied phenomenon, which we will not pursue here.

### 5.2.5 The role of instantons

There is another way to think about the breaking of the \( U(1) \) symmetry and \( \theta \)-dependence in this theory. If one considers the Euclidean functional integral, it is
natural to look for stationary points of the integration, i.e.

for classical solutions of the Euclidean equations of motion. In order that they be potentially important, it is necessary that these solutions have finite action, which means that they must be localized in Euclidean space and time. For this reason, such solutions were dubbed "instantons" by 't Hooft. Such solutions are not difficult to find in the $\text{CP}^N$ model; we will describe them below. These solutions carry non-zero values of the topological charge,

$$\frac{1}{2\pi} \int d^2 x \epsilon_{\mu\nu} F_{\mu\nu} = n,$$

and have an action $2\pi n$. If we write $z_i = z_{i\text{cl}} + \delta z_i$, the functional integral, in the presence of a $\theta$ term, has the form:

$$Z_{\text{inst}} = e^{\frac{-2\pi n}{\theta}} e^{i\theta \int [d\delta z_j] e^{-\delta z_i \frac{\delta^2 S}{\delta z_i \delta z_j}} + \cdots}. \tag{5.55}$$

It is easy to construct the instanton solution in the case of $\text{CP}^1$. Rather than write the theory in terms of a gauge field, as we have done above, it is convenient to parameterize the theory in terms of a single complex field, $Z$. One can, for example, define $Z = z_1/z_2$, and let $\bar{Z}$ denote its complex conjugate. Then, with a bit of algebra, one can show that the action for $Z$ which follows from Eq. (5.45) takes the form (it is easiest to work backwards, starting with the equation below and deriving Eq. (5.45)):

$$L = \frac{\partial_{\mu} Z \partial_{\mu} \bar{Z}}{(1 + \bar{Z}Z)^2}. \tag{5.56}$$

The function

$$g_{Z\bar{Z}} = \frac{1}{(1 + ZZ)^2} \tag{5.57}$$

has an interesting significance. There is a well-known mapping of the unit sphere, $x_1^2 + x_2^2 + x_3^2$, onto the complex plane:

$$z = \frac{x_1 + i x_2}{1 - x_3}. \tag{5.58}$$

The inverse is

$$x_1 = \frac{z + z^*}{1 + |z|^2}, \quad x_2 = \frac{z - z^*}{i(1 + |z|^2)}, \quad x_3 = \frac{|z|^2 - 1}{|z|^2 + 1}. \tag{5.59}$$

The line element on the sphere is mapped in a non-trivial way onto the plane:

$$ds^2 = dx_1^2 + dx_2^2 + dx_3^2 = g_{z\bar{z}} dz d\bar{z} = \frac{1}{(1 + z\bar{z})^2} dz d\bar{z}. \tag{5.60}$$
Anomalies, instantons and the strong CP problem

So the model describes a field constrained to move on a sphere; \( g \) is the metric of the sphere. In general, such a model is called a non-linear sigma model. This is an example of a Kahler geometry, a type of geometry which will figure significantly in our discussion of string compactification.

It is straightforward to write down the equations of motion:

\[
\partial^2 Z g_{Z\bar{Z}} + \partial_\mu Z \left( \partial_\mu \frac{\partial g}{\partial Z} + \partial_\mu \phi \frac{\partial g}{\partial \bar{Z}} \right) = 0,
\]

or

\[
\partial_z \partial_{\bar{z}} Z - \frac{2 \partial_z Z \partial_{\bar{z}} \bar{Z}}{1 + \bar{Z}Z} = 0.
\]

Now calling the space-time coordinates \( z = x_1 + ix_2, z^* = x_1 - ix_2 \), we see that if \( Z \) is analytic, the equations of motion are satisfied! So a simple solution, which you can check has finite action, is

\[
Z(\bar{z}) = \rho \bar{z}.
\]

In addition to evaluating the action, you can evaluate the topological charge,

\[
\frac{1}{2\pi} \int d^2 x \epsilon_{\mu\nu} F^{\mu\nu} = 1
\]

for this solution. More generally, the topological charge measures the number of times that \( Z \) maps the complex plane into the complex plane; \( Z = z^n \) has charge \( n \).

We can generalize these solutions. The solution of Eq. (5.63) breaks several symmetries of the action: translation invariance, two-dimensional rotational invariance, and the scale invariance of the classical equations. So we should be able to generate new solutions by translating, rotating and dilating the solution. You can check that

\[
Z(z) = \frac{az + b}{cz + d}
\]

is a solution with action \( 2\pi \). The parameters \( a, \ldots, d \) are called collective coordinates. They correspond to the symmetries of translations, dilations, and rotations, and special conformal transformations (forming the group \( SL(2, C) \)). In other words, any given finite-action solution breaks the symmetries. In the path integral, the symmetry of Green’s functions is recovered when one integrates over the collective coordinates. For translations, this is particularly simple. Integrating over \( X_0 \), the instanton position,

\[
\langle Z(x)Z(y) \rangle \approx \int d^2 x_0 \phi_{cl}(x - x_0)\phi_{cl}(y - x_0)e^{-S_0}.
\]
(The precise measure is obtained by the Faddeev–Popov method.) Similarly, the integration over the parameter $\rho$ yields a factor

$$
\int d\rho \rho^{-1} e^{-\frac{2\pi}{\rho^2} \cdots}
$$

(5.67)

Here the first factor follows on dimensional grounds. The second follows from renormalization-group considerations. It can be found by explicit evaluation of the functional determinant. Note that, because of asymptotic freedom, this means that typical Green functions will be divergent in the infrared.

There are many other features of this instanton one can consider. For example, one can add massless fermions to the model. The resulting theory has a chiral $U(1)$ symmetry, which is anomalous. The instanton gives rise to non-zero Green functions which violate the $U(1)$ symmetry. We will leave investigation of fermions in this model to the exercises, and turn to the theory of interest, which exhibits phenomena parallel to this simple theory.

### 5.3 Real QCD

The model of the previous section mimics many features of real QCD. Indeed, we will see that much of our discussion can be carried over, almost word for word, to the observed strong interactions. This analogy is helpful, given that in QCD we have no approximation which gives us control over the theory comparable to that which we found in the large-$N$ limit of the $\mathbb{C}P^N$ model. As in that theory, we have the following.

- There is a $\theta$ parameter, which appears as an integral over the divergence of a non-gauge invariant current.
- There are instantons, which indicate that physical quantities should be $\theta$-dependent. However, instanton effects cannot be considered in a controlled approximation, and there is no clear sense in which $\theta$-dependence can be understood as arising from instantons.
- In QCD, there is also a large-$N$ expansion, but while it produces significant simplification, one cannot solve the theory even in the leading large-$N$ approximation. Instead, understanding of the underlying symmetries, and experimental information about chiral symmetry breaking, provides critical information about the behavior of the strongly coupled theory, and allows computations of the physical effects of $\theta$.

#### 5.3.1 The theory and its symmetries

In order to understand the effects of $\theta$, it is sufficient to focus on only the light quark sector of QCD. For simplicity in writing some of the formulas, we will consider two light quarks; it is not difficult to generalize the resulting analysis to the case of
three. It is believed that the masses of the $u$ and $d$ quarks are of order 5 MeV and 10 MeV, respectively, much smaller than the scale of QCD. So we first consider an idealization of the theory in which these masses are set to zero. In this limit, the theory has a symmetry $SU(2)_L \times SU(2)_R$. Calling

$$q = \begin{pmatrix} u \\ d \end{pmatrix}, \quad \bar{q} = \begin{pmatrix} \bar{u} \\ \bar{d} \end{pmatrix},$$

(5.68)

the two $SU(2)$ symmetries act separately on $q$ and $\bar{q}$ (thought of as left-handed fermions),

$$q^T \rightarrow q^T U_L \quad \bar{q} \rightarrow U_R \bar{q}.$$

(5.69)

This symmetry is spontaneously broken. The order parameter for the symmetry breaking is believed to be an expectation value for the quark bilinear:

$$\mathcal{M} = \bar{q} q.$$

(5.70)

Under the original symmetry,

$$\mathcal{M} \rightarrow U_R \mathcal{M} U_L.$$

(5.71)

The expectation value (condensate) of $\mathcal{M}$ is

$$\mathcal{M} = c \Lambda_{\text{qcd}}^3 \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}.$$

(5.72)

This breaks some of the original symmetry, but preserves the symmetry $U_L = U_R$. This symmetry is just the $SU(2)$ of isospin. The Goldstone bosons associated with the three broken symmetry generators must transform in a representation of the unbroken symmetry: these are just the pions, which are a vector of isospin. One can think of the Goldstone bosons as being associated with a slow variation of the expectation value in space, so we can introduce a composite operator

$$\mathcal{M} = \bar{q} q = M_0 e^{i \tau_1 \tau_2 f_{\pi} \left( \begin{array}{cc} 1 & 0 \\ 0 & 1 \end{array} \right)}.$$

(5.73)

The quark mass term in the Lagrangian is then (for simplicity taking $m_u = m_d = m_q$)

$$m_q M.$$

(5.74)

Replacing $\mathcal{M}$ by its expression (5.73) gives a potential for the pion fields. Expanding $\mathcal{M}$ in powers of $\pi/f_{\pi}$, the minimum of the potential occurs for $\pi_a = 0$. Expanding to second order, one has

$$m_{\pi}^2 f_{\pi}^2 = m_q M_0.$$

(5.75)
We have been a bit cavalier about the symmetries. The theory also has two $U(1)$ symmetries:

\begin{align}
q &\rightarrow e^{i\alpha} q \quad \bar{q} \rightarrow e^{i\alpha} \bar{q} \\
q &\rightarrow e^{i\alpha} q \quad \bar{q} \rightarrow e^{-i\alpha} \bar{q}
\end{align}

The first of these is baryon number and it is not chiral (and is not broken by the condensate). The second is the axial $U(1)_5$; it is also broken by the condensate. So, in addition to the pions, there should be another approximate Goldstone boson. But there is no good candidate among the known hadrons. The $\eta$, has the right quantum numbers, but, as we will see below, the $\eta$ is too heavy to be interpreted in this way. The absence of this fourth (or, in the case of three light quarks, ninth) Goldstone boson is called the $U(1)$ problem.

The $U(1)_5$ symmetry suffers from an anomaly, however, and we might hope that this has something to do with the absence of a corresponding Goldstone boson. The anomaly is given by

\[ \partial_\mu j_5^\mu = \frac{1}{16\pi^2} F \tilde{F}. \]

Again, we can write the right-hand side as a total divergence,

\[ F \tilde{F} = \partial_\mu K^\mu, \]

where

\[ K^\mu = \epsilon_{\mu\nu\rho\sigma} \left( A^a_\nu F^a_{\rho\sigma} - \frac{2}{3} f^{abc} A^a_\nu A^b_\rho A^c_\sigma \right). \]

This accounts for the fact that in perturbation a theory the axial $U(1)$ is conserved. Non-perturbatively, as we will now show, there are important configurations in the functional integral for which the right-hand side does not vanish rapidly at infinity.

### 5.3.2 Instantons in QCD

In the Euclidean functional integral

\[ Z = \int [dA][dq][d\bar{q}] e^{-S} \]

it is natural to look for stationary points of the effective action, i.e. finite action, classical solutions of the theory in imaginary time. The Yang–Mills equations are complicated, non-linear equations, but it turns out that, much as in the CP$^N$ model, the instanton solutions can be found rather easily. The following tricks simplify the construction, and turn out to yield the general solution. First, note that the
Yang–Mills action satisfies an inequality, the Bogomolny bound:

$$\int (F \pm \tilde{F})^2 = \int (F^2 + \tilde{F}^2 \pm 2F \tilde{F}) = \int (2F^2 + 2F \tilde{F}) \geq 0. \quad (5.82)$$

So the action is bounded by $\int F \tilde{F}$, with the bound being saturated when

$$F = \pm \tilde{F} \quad (5.83)$$

i.e. if the gauge field is (anti-) self-dual. This equation is a first-order equation, and it is easy to solve if one first restricts to an $SU(2)$ subgroup of the full gauge group. One makes the ansatz that the solution should be invariant under a combination of ordinary rotations and global $SU(2)$ gauge transformations:

$$A_\mu = f(r^2) + h(r^2) \vec{x} \cdot \vec{\tau} \quad (5.84)$$

where we are using the matrix notation for the gauge fields. One can actually make a better guess: define the gauge transformation

$$g(x) = \frac{x_4 + i \vec{x} \cdot \vec{\tau}}{r} \quad (5.85)$$

and take

$$A_\mu = f(r^2) g \partial_\mu g^{-1}. \quad (5.86)$$

Then plugging in the Yang–Mills equations yields:

$$f = \frac{-ir^2}{r^2 + \rho^2} \quad (5.87)$$

where $\rho$ is an arbitrary quantity with dimensions of length. The choice of origin here is also arbitrary; this can be remedied by simply replacing $x \to x - x_0$ everywhere in these expressions, where $x_0$ represents the location of the instanton.

From this solution, it is clear why $\int \partial_\mu K^\mu$ does not vanish for the solution: while $A$ is a pure gauge at infinity, it falls only as $1/r$. Indeed, since $F = \tilde{F}$, for this solution

$$\int F^2 = \int \tilde{F}^2 = 32\pi^2. \quad (5.88)$$

This result can also be understood topologically. Note that $g$ defines a mapping from the “sphere at infinity” into the gauge group. It is straightforward to show that

$$\frac{1}{32\pi^2} \int d^4x F \tilde{F} \quad (5.89)$$

1 This is not an accident, nor was the analyticity condition in the CP$^N$ case. In both cases, we can add fermions so that the model is supersymmetric. Then one can show that if some of the supersymmetry generators, $Q_\alpha$, annihilate a field configuration, then the configuration is a solution. This is a first-order condition; in the Yang–Mills case, it implies self-duality, and in the CP$^N$ case it requires analyticity.
counts the number of times $g$ maps the sphere at infinity into the group (one for this specific example; $n$ more generally). In the exercises and suggested reading, features of the instanton are explored in more detail.

So we have exhibited potentially important contributions to the path integral which violate the $U(1)$ symmetry. How does this violation of the symmetry show up? Let’s consider the path integral more carefully. Having found a classical solution, we want to integrate about small fluctuations about it. Including the $\theta$ term, these have the form

$$\langle \bar{u}ud\rangle = e^{-\frac{8\pi^2}{\alpha^2}} e^{i\theta} \int [d\delta A][dq][d\bar{q}] \exp \left(-\frac{\delta^2 S}{\delta A^2} \delta A^2 - S_{q,\bar{q}}\right) \bar{u}ud\theta.$$  

(5.90)

Now $S$ contains an explicit factor of $1/g^2$. As a result, the fluctuations are formally suppressed by $g^2$ relative to the leading contribution. The one-loop functional integral yields a product of determinants for the fermions, and of inverse square root determinants for the bosons.

Consider the integral over the fermions. It is straightforward, if challenging, to evaluate the determinants. But if the quark masses are zero, the fermion functional integrals are zero, because there is a zero mode for each of the fermions, i.e. for both $q$ and $\bar{q}$ there is a normalizable solution of the equation:

$$D\bar{u} = 0 \quad D\bar{u} = 0 \quad (5.91)$$

and similarly for $d$ and $\bar{d}$. It is straightforward to construct these solutions:

$$u = \frac{\rho}{(\rho^2 + (x-x_0)^2)^{3/2}}\zeta,$$

(5.92)

where $\zeta$ is a constant spinor, and similarly for $\bar{u}$, etc.

Let’s understand this a bit more precisely. Euclidean path integrals are conceptually simple. Consider some classical solution, $\Phi_{cl}(x)$ (here $\Phi$ denotes collectively the various bosonic fields; we will treat, for now, the fermions as vanishing in the classical solutions). In the path integral, at small coupling, we are interested in small fluctuations about the classical solution,

$$\Phi = \Phi_{cl} + \delta \Phi.$$  

(5.93)

Because the action is stationary at the classical solution,

$$S = S_{cl} + \int d^4 x \delta \Phi \frac{\partial^2 L}{\partial \Phi^2} \delta \Phi + \cdots.$$  

(5.94)

The second derivative here is a shorthand for a second-order differential operator, which we will simply denote by $S''$, and refer to as the quadratic fluctuation operator. We can expand $\delta \Phi$ in (normalizable) eigenfunctions of this operator $\Phi_n$ with eigenvalues $\lambda_n$, $\Phi = c_n \Phi_n$. The result of the functional integral is then $\prod \lambda_n^{-1/2}$. 

5.3 Real QCD

This is the leading correction to the classical limit. Higher-order corrections are suppressed by powers of \( g^2 \). This is most easily seen by working in the scaling where the action has a \( 1/g^2 \) out front. Then one can derive the perturbation theory from the path integral in the usual way; the main difference from the usual treatment with zero background fields is that the propagators are more complicated. The propagators for various fields in the instanton background are in fact known in closed form.

The form of the differential operator is familiar from our calculation of the \( \beta \)-function in the background field method (in the background field gauge). For the gauge bosons, in a suitable (‘background field’) gauge, it is

\[
S'' = D^2 + J_{\mu\nu} F^{\mu\nu}.
\]  

(5.95)

Here \( D \) is just the covariant derivative with the vector potential corresponding to the classical solution (instanton), and similarly for the field strength; \( J_{\mu\nu} \) is the generator of Lorentz transformations in the vector representation. The eigenvalue problem was completely solved by ’t Hooft.

Both the bosonic and fermionic quadratic fluctuation operators have zero eigenvalues. For the bosons, these potentially give infinite contributions to the functional integral, and they must be treated separately. The difficulty is that among the variations of the fields are symmetry transformations: changes in the location of the instanton (translations), rotations of the instanton, and scale transformations. Consider translations. For every solution, there is an infinite set of solutions obtained by shifting the origin (varying \( x_0 \)). Instead of integrating over a coefficient, \( c_0 \), we integrate over the collective coordinate \( x_0 \) (one must also include a suitable Jacobian factor). The effect of this is to restore translational invariance in Green’s functions. We will see this explicitly shortly. Similarly, the instanton breaks the rotational invariance of the theory. Correspondingly, we can find a three-parameter set of solutions and zero modes. Integrating over these rotational collective coordinates restores rotational invariance. (The instanton also breaks a global gauge symmetry, but a combination of rotations and gauge transformations is preserved.)

Finally, the classical theory is scale invariant; this is the origin of the parameter \( \rho \) in the solution. Again, one must treat \( \rho \) as a collective coordinate, and integrate over \( \rho \). There is a power of \( \rho \) arising from the Jacobian, which can be determined on dimensional grounds. For the Green function, Eq. (5.90), for example, which has dimension six, we have (if all of the fields are evaluated at the same point),

\[
\int d\rho \rho^{-7}.
\]  

(5.96)

However, there is additional \( \rho \)-dependence because the quantum theory violates the scale symmetry. This can be understood by replacing \( g^2 \to g^2(\rho) \) in the functional
5.3 Real QCD

integral, and using

\[ e^{-8\pi^2 g^2(\rho)} \approx (\rho M)^{b_0} \]  

(5.97)

for small \( \rho \). For three-flavor QCD, for example, \( b_0 = 9 \), and the \( \rho \) integral diverges for large \( \rho \). This is just the statement that the integral is dominated by the infrared, where the QCD coupling becomes strong.

Fermion functional integrals introduce a new feature. In four-component language, it is necessary to treat \( q \) and \( \bar{q} \) as independent fields. This rule gives the functional integral as a determinant, rather than as, say, the square root of a determinant. (In two-component language, this corresponds to treating \( q \) and \( q^* \) as independent fields.) So at one-loop order, we need to study:

\[ \bar{\mathcal{D}} q_n = \lambda_n q_n \quad \bar{\mathcal{D}} \bar{q}_n = \lambda_n \bar{q}_n \]  

(5.98)

For non-zero \( \lambda_n \) there is a pairing of solutions with opposite eigenvalues of \( \gamma_5 \). In four-component notation, one can see this from:

\[ \bar{\mathcal{D}} q_n = \lambda_n q_n \rightarrow \bar{\mathcal{D}} \gamma_5 q_n = -\lambda_n \gamma_5 q_n. \]  

(5.99)

Zero eigenvalues, however, are special. There is no corresponding pairing. This has implications for the fermion functional integral. Writing

\[ q(x) = \sum a_n q_n(x), \]  

(5.100)

\[ S = \sum \lambda_n a_n^* a_n. \]  

(5.101)

Then

\[ \int [dq][d\bar{q}] e^{-S} = \prod_{n=0}^{\infty} da_n da_n^* e^{-\sum_{n \neq 0} \lambda_n a_n^* a_n}. \]  

(5.102)

Because the zero modes do not contribute to the action, many Green functions vanish. For example, \( \langle 1 \rangle = 0 \). In order to obtain a non-vanishing result, we need enough insertions of \( q \) to “soak up” all of the zero modes.

We have seen that, in the instanton background, there are normalizable fermion zero modes, one for each left-handed field. This means that in order for the path integral to be non-vanishing, we need to include insertions of enough \( q \)s and \( \bar{q} \)s to soak up all of the zero modes. In other words, in two-flavor QCD, non-vanishing Green functions have the form

\[ \langle \bar{u}u\bar{d}d \rangle \]  

(5.103)

and violate the symmetry. Note that the symmetry violation is just as predicted from the anomaly equation:

\[ \Delta Q_5 = \frac{2}{16\pi^2} \int d^4xF\tilde{F} = 4. \]  

(5.104)
This is a particular example of an important mathematical theorem known as the Atiyah–Singer index theorem.

We can put all of this together to evaluate a Green function which violates the classical $U(1)$ symmetry of the massless theory, $\langle \bar{u}(x)u(x)d(x)d(x) \rangle$. Taking the gauge group to be $SU(2)$, there is one zero mode for each of $u$, $\bar{u}$, $d$ and $\bar{d}$. The fields in this expectation value can soak up all of these zero modes. The effect of the integration over $x_0$ is to give a result independent of $x$, since the zero modes are functions only of $x - x_0$. The integration over the rotational zero modes gives a non-zero result only if the Lorentz indices are contracted in a rotationally invariant manner (the same applies to the gauge indices). The integration over the instanton scale size – the conformal collective coordinate – is more problematic, exhibiting precisely the infrared divergence of Eq. (5.96).

So we have provided some evidence that the $U(1)$ problem is solved in QCD, but no reliable calculation. What about $\theta$-dependence? Let us ask first about $\theta$-dependence of the vacuum energy. In order to get a non-zero result, we need to allow that the quarks are massive. Treating the mass as a perturbation, we obtain a result of the form:

$$E(\theta) = CA_{\text{QCD}}^9 m_u m_d \cos(\theta) \int d\rho \rho^{-3} \rho^9.$$  \hspace{1cm} (5.105)

So, as in the CP$^N$ model, we have evidence for $\theta$-dependence, but cannot do a reliable calculation. That we cannot do a calculation should not be a surprise. There is no small parameter in QCD to use as an expansion parameter. Fortunately, we can use other facts which we know about the strong interactions to get a better handle on both the $U(1)$ problem and the question of $\theta$-dependence.

Before continuing, however, let us consider the weak interactions. Here there is a small parameter, and there are no infrared difficulties, so we might expect instanton effects to be small. The analog of the $U(1)$ symmetry in this case is baryon number. Baryon number has an anomaly in the standard model, since all of the quark doublets have the same sign of the baryon number. ’t Hooft showed that one could actually use instantons, in this case, to compute the violation of baryon number. Technically, there are no finite-action Euclidean solutions in this theory; this follows, as we will see in a moment, from a simple scaling argument. However, ’t Hooft realized that one can construct important configurations of non-zero topological charge by starting with the instantons of the pure gauge theory and perturbing them. For the Higgs boson, one solves the equation

$$D^2 \phi = V'(\phi).$$  \hspace{1cm} (5.106)
For a light boson, one can neglect the right-hand side. Then this equation is solved by:

\[ \phi(x) = i \bar{\sigma}^\mu x^\mu \left( \frac{1}{x^2 + \rho^2} \right)^{\frac{1}{2}} \langle \phi \rangle. \]  

(5.107)

Note that at large \( x \), this has the form \( g(x) \langle \phi \rangle \). As a result, the action of the configuration is finite. One finds a correction to the action

\[ \delta S = \frac{1}{g^2} v^2 \rho^2. \]  

(5.108)

Including this in the exponential damps the \( \rho \) integral at large \( \rho \), and leads to a convergent result.

Including now the fermions, there is a zero mode for each \( SU(2) \) doublet. So one obtains a non-zero expectation value for correlation functions of the form \( \langle QQQLLL \rangle \), where the color and \( SU(2) \) indices are contracted in a gauge invariant way, and the flavors for the \( Q \)s and \( L \)s are all different. The coefficient has the form:

\[ A_{bv} = C e^{-\frac{2\pi}{\alpha_w}}. \]  

(5.109)

From this, one can see that baryon number violation occurs in the Standard Model, but at an incredibly small rate. One can also calculate a term in the effective action, involving three quarks and three leptons, with a similar coefficient, by studying Green functions in which all of the fields are widely separated. We will encounter this sort of computation later, when we discuss instantons in supersymmetric theories.

### 5.3.3 Physical interpretation of the instanton solution

We have derived dramatic physical effects from the instanton solution by direct calculation, but we have not provided a physical picture of the phenomena the instanton describes. Already in quantum mechanics, imaginary time solutions of the classical equations of motion are familiar in the WKB analysis of tunneling, and the Yang–Mills instanton (and the \( CP^N \) instanton) also describe tunneling phenomena. In this section, we will confine our attention to pure gauge theories. The generalization to theories with fermions and/or scalars is straightforward and interesting.

To understand the instanton as tunneling, it is helpful to work in a non-covariant gauge, in which there is a Hamiltonian description. Already in quantum mechanics, imaginary time solutions of the classical equations of motion are familiar in the WKB analysis of tunneling, and the Yang–Mills instanton (and the \( CP^N \) instanton) also describe tunneling phenomena. In this section, we will confine our attention to pure gauge theories. The generalization to theories with fermions and/or scalars is straightforward and interesting.
Gauss’s law, which is now to be viewed as an operator constraint on states. For example, in a $U(1)$ theory,

$$G(\vec{x})|\Psi\rangle = (\vec{\nabla} \cdot \vec{E} - \rho)|\Psi\rangle = 0. \quad (5.110)$$

The left-hand side is almost the generator of gauge transformations. On the gauge fields, for example,

$$\left[ \int d^3 x \omega(\vec{x}) G(\vec{x}), A_i(\vec{y}) \right] = - \int d^3 x \partial_j \omega(\vec{x}) [E(\vec{x})_j, A(\vec{y})_i] = \partial_i \omega(\vec{y}). \quad (5.111)$$

In the second step we integrated by parts and dropped a possible surface term. This requires that $\omega \to 0$ fast enough at infinity. Such gauge transformations are called “small” gauge transformations. We have learned that in $A_0 = 0$ gauge, states must be invariant under time-independent, small gauge transformations.

In electrodynamics, this is not particularly interesting. But the same manipulations hold in non-Abelian theories, and in this case there are interesting large gauge transformations. An example is

$$g(\vec{x}) = \exp \left( i \pi \frac{\vec{x} \cdot \vec{\sigma}}{\sqrt{x^2 + a^2}} \right). \quad (5.112)$$

We can also consider powers of $g$, $g^n$. We can think of $g$ as mapping the three-dimensional space into the group $SU(2)$. The number of times that the mapping wraps around the gauge group is known as the winding number, and it can be written as:

$$n = \frac{1}{24\pi^2} \int d^3 x \epsilon_{ijk} \text{Tr}[\partial_i g \partial_j g \partial_k g]. \quad (5.113)$$

However, $g_n$ is not unique; we can multiply by any small gauge transformation without changing $n$. The zero energy states consist of $A_i = ig^{-n} \partial_i g^n$, averaged over the small gauge transformations so as to make them invariant.

With just a little algebra, one can show that $n = \int d^3 x K_0$, where $K^\mu$ is the topological current we encountered in Eq. (5.80). So an instanton, in $A_0 = 0$ gauge, corresponds to a tunneling between states of different $n$. More precisely, there is a non-zero matrix element of the Hamiltonian between states of different $n$,

$$\langle n | H | n \pm 1 \rangle = \epsilon. \quad (5.114)$$

This is analogous to the situation in crystals, and the energy eigenstates are similar to Bloch waves:

$$|\theta\rangle = \sum_n e^{in\theta} |n\rangle, \quad (5.115)$$
with energy $\epsilon \cos(\theta)$. This $\theta$ is precisely the same $\theta$ which entered as a parameter in the Lagrangian.

### 5.3.4 QCD and the $U(1)$ problem

In real QCD, we have seen that, on the one hand, instanton configurations violate the axial $U(1)$ symmetry. On the other hand, the explicit calculations are infrared-divergent, so we cannot make a reliable calculation of the Goldstone mass. This is not a surprise; there is no small parameter which would justify the use of a semiclassical approximation. Still, the instanton analysis we have described makes clear that there is no reason to expect that there is a light Goldstone boson. Actually, while perturbative and semiclassical (instanton) techniques have no reason to give reliable results, there are two approximation methods techniques which are available. The first is large $N$, where one now allows the $N$ of $SU(N)$ to be large, with $g^2 N$ fixed. In contrast to the case of $\mathbb{CP}^N$, this does not permit enough simplification to permit explicit computations, but it does allow one to make qualitative statements about the theory. Witten has pointed out a way in which one can relate the mass of the $\eta$ (or $\eta'$ if one is thinking in terms of $SU(3) \times SU(3)$ current algebra) to quantities in a theory without quarks. The anomaly is an effect suppressed by a power of $N$, in the large $N$ limit. This is because the loop diagram contains a factor of $g^2$ but not of $N$. So, in large $N$, it can be treated as a perturbation, and the $\eta$ is almost massless. The $\partial_\mu j_5^\mu$ is like a creation operator for $\eta$, so (just like $\partial_\mu j_3^\mu$ is a creation operator for the $\pi$ meson), so one can compute the mass if one knows the correlation function, at zero momentum,

$$\langle \partial_\mu j_5^\mu(x) \partial_\mu j_5^\mu(y) \rangle \propto \frac{1}{N^2} \langle F(x) \tilde{F}(x) F(y) \tilde{F}(y) \rangle. \quad (5.116)$$

To leading order in the $1/N$ expansion, the $F \tilde{F}$ correlation function can be computed in the theory without quarks. Witten argued that while this vanishes order by order in perturbation theory, there is no reason that this correlation function need vanish in the full theory. Attempts have been made to compute this quantity both in lattice gauge theory and using the AdS–CFT correspondence recently discovered in string theory. Both methods give promising results.

So the $U(1)$ problem should be viewed as solved, in the sense that absent any argument to the contrary, there is no reason to think that there should be an extra Goldstone boson in QCD.

The second approximation scheme which gives some control of QCD is known as chiral perturbation theory. The masses of the $u$, $d$ and $s$ quarks are small compared to the QCD scale, and the mass terms for these quarks in the Lagrangian can be treated as perturbations. This will figure in our discussion in the next section.
5.4 The strong CP problem

5.4.1 The $\theta$-dependence of the vacuum energy

The fact that the anomaly resolves the $U(1)$ problem in QCD raises another issue. Given that $\int d^4x F \tilde{F}$ has physical effects, a theta term in the action has physical effects as well. Since this term is CP odd, this means that there is the potential for strong CP-violating effects. These effects should vanish in the limit of zero quark masses, since in this case, by a field redefinition, we can remove $\theta$ from the Lagrangian. In the presence of quark masses, the $\theta$-dependence of many quantities can be computed. Consider, for example, the vacuum energy. In QCD, the quark mass term in the Lagrangian has the form:

$$L_m = m_u \bar{u}u + m_d \bar{d}d + h.c. \quad (5.117)$$

Were it not for the anomaly, we could, by redefining the quark fields, take $m_u$ and $m_d$ to be real. Instead, we can define these fields so that there is no $\theta F \tilde{F}$ term in the action, but there is a phase in $m_u$ and $m_d$. Clearly, we have some freedom in making this choice. In the case that $m_u$ and $m_d$ are equal, it is natural to choose these phases to be the same. We will explain shortly how one proceeds when the masses are different (as they are in nature). So

$$L_m = (m_u \bar{u}u + m_d \bar{d}d)e^{i\theta} + h.c. \quad (5.118)$$

Now we want to treat this term as a perturbation. At first order, it makes a contribution to the ground-state energy proportional to its expectation value. We have already argued that the quark bilinears have non-zero vacuum expectation values, so

$$E(\theta) = (m_u + m_d) \cos(\theta) \langle \bar{q}q \rangle. \quad (5.119)$$

While, without a difficult non-perturbative calculation, we can’t calculate the separate quantities on the right-hand side of this expression, we can, using current algebra, relate them to measured quantities. We have seen (Appendix B) that

$$m_\pi^2 f_\pi^2 = \text{Tr} M_q \langle \Sigma \rangle = (m_u + m_d) \langle \bar{q}q \rangle \quad (5.120)$$

Replacing the quark mass terms in the Lagrangian by their expectation values, we can immediately read off the energy of the vacuum as a function of $\theta$:

$$E(\theta) = m_\pi^2 f_\pi^2 \cos(\theta). \quad (5.121)$$

This expression can readily be generalized to the case of three light quarks by similar methods. So we see that there is real physics in $\theta$, even if we don’t understand how to do an instanton calculation. In the next section, we will calculate a more interesting quantity: the neutron electric dipole moment as a function of $\theta$. 
5.4 The strong CP problem

5.4.2 The neutron electric dipole moment

The most interesting physical quantities to study in connection with CP violation are electric dipole moments, particularly that of the neutron, $d_n$. If CP were badly violated in the strong interactions, one might expect $d_n \approx e \text{fm} \approx 10^{-14} \text{ cm}$. But the experimental limits on the dipole moment are striking,

$$d_n < 10^{-25} \text{ e cm.} \quad (5.122)$$

Using current algebra, the leading contribution to the neutron electric dipole moment due to $\theta$ can be calculated, and one obtains a limit $\theta < 10^{-9}$. Here we outline the main steps in the calculation; I urge you to work out the details following the reference in the suggested reading. We will simplify the analysis by working in an exact $SU(2)$-symmetric limit, i.e. by taking $m_u = m_d = m$. We again treat the Lagrangian of Eq. (5.118) as a perturbation. We can understand how this term depends on the $\pi$ fields by making an axial $SU(2)$ transformation on the quark fields. In other words, a background $\pi$ field can be thought of as a small chiral transformation on the vacuum. Then, for example, for the $\tau_3$ direction, $q \to (1 + i \pi \tau_3)q$ (the $\pi$ field parameterizes the transformation), so the action becomes:

$$\frac{m_{\pi}}{f_\pi} \pi_3 \left( \bar{q} \gamma_5 q + \theta \bar{q} q \right). \quad (5.123)$$

The second term is a CP-violating coupling of the mesons to the pions.

This coupling is difficult to measure directly, but this coupling gives rise, in a calculable fashion, to a neutron electric dipole moment. Consider the graph of Fig. 5.2. This graph generates a neutron electric dipole moment, if we take one coupling to be the standard pion–nucleon coupling, and the second the coupling we have computed above. The resulting Feynman graph is infrared divergent; we cut this off at $m_\pi$, while cutting off the integral in the ultraviolet at the QCD scale. The low-energy calculation is reliable in the limit that $m_\pi$ is small, so that $\ln(m_\pi/\Lambda_{\text{QCD}})$ is large compared to one. The result is:

$$d_n = g_{NNN} \frac{-\theta m_u m_d}{f_\pi (m_u + m_d)} \langle N_f | \bar{q} \tau^a q | N_i \rangle \ln(M_N/m_\pi) \frac{1}{4\pi^2} M_N. \quad (5.124)$$
The matrix element can be estimated using the $SU(3)$ symmetry of Gell-Mann and Ne'eman, yielding $d_n = 5.2 \times 10^{-16} \theta$ cm. The experimental bound gives $\theta < 10^{-9} - 10^{-10}$. Understanding why CP violation is so small in the strong interactions is the “strong CP problem.”

### 5.5 Possible solutions of the strong CP problem

What should our attitude towards this problem be? We might argue that, after all, some Yukawa couplings are as small as $10^{-5}$, so why is $10^{-9}$ so bad? On the other hand, we suspect that the smallness of the Yukawa couplings is related to approximate symmetries, and that these Yukawa couplings are telling us something. Perhaps there is some explanation of the smallness of $\theta$, and perhaps this is a clue to new physics. In this section we review some of the solutions which have been proposed to understand the smallness of $\theta$.

#### 5.5.1 When $m_u = 0$

Suppose that the mass of the up quark were zero. In this case, by a field redefinition of the up quark,

$$u \rightarrow e^{-i\theta} u,$$

one could make the $\theta$ term vanish as a consequence of the anomaly. This is a simple enough explanation, but there are two issues. First, why? We could imagine that this is the result of a symmetry, but this symmetry cannot be a real symmetry of the underlying theory, since it is violated by QCD (through the anomaly). We will see later in this book that discrete symmetries, with anomalies of the kind required to understand a vanishing up quark mass, do frequently arise in string theory. So perhaps this sort of explanation is plausible.

There is a much more practical issue which arises from the phenomenology of QCD itself. Standard studies of QCD current algebra give the non-zero value of $m_u$ which we quoted earlier, around 5 MeV. This, by itself, is not necessarily a serious objection. The question is: at what momentum transfer is the mass evaluated? Suppose, for example, that this is the up quark mass at 300 MeV, while the mass of the u quark at, say, 10 GeV is essentially zero. Integrating out physics between the scale 10 GeV and 0.3 GeV will induce a u quark mass in the effective Lagrangian. Instantons will generate such a term. It will be necessary to soak up the d and s quark zero modes with the d and s quark mass terms, so the u quark mass will be proportional to $m_d m_s$. We can’t actually do a reliable calculation, but we would expect:

$$m_u = \frac{m_d m_s}{300 \text{ MeV}},$$

(5.126)
which is not much different than the usual current algebra number. At this point, however, numerical lattice calculations are good enough to address this issue, and a massless $u$ quark at several GeV appears to be incompatible with the data.

### 5.5.2 Spontaneous CP violation

Suppose that the underlying theory respects CP, and the observed CP violation is spontaneous. Because $\theta$ is CP odd, the underlying theory has $\theta = 0$. One might hope that this feature would be preserved when the symmetry is spontaneously broken.

There are a number of ways that $\theta$ might be generated in the low-energy theory. First, suppose that CP is broken by the expectation value of a complex field, $\Phi$. There might well be direct couplings, such as

$$\frac{1}{16\pi^2} \text{Im} \Phi F \tilde{F}.$$  \hspace{1cm} (5.127)

Note that $\Phi$ might also couple to fermions, giving them a large mass through its expectation value. When these fermions are integrated out, this would also generate an effective $\theta$. This is likely simply given the anomalous field redefinitions which may be required to make the masses of these fields real. It is possible to construct models where, at least at tree level, the heavy fermion mass matrices are real. Quantum corrections, and the couplings mentioned above, pose additional challenges. It is an open question whether such an explanation of the smallness of $\theta$ is plausible, and has testable consequences.

### 5.5.3 The axion

Perhaps the most compelling explanation of the smallness of $\theta$ involves a hypothetical particle called the axion. We present here a slightly updated version of the original idea of Peccei and Quinn.

Consider the vacuum energy as a function of $\theta$ (Eq. (5.119)). This energy has a minimum at $\theta = 0$, i.e. at the CP conserving point. As Weinberg noted long ago, this is almost automatic: points of higher symmetry are necessarily stationary points. As it stands, this observation is not particularly useful, since $\theta$ is a parameter, not a dynamical variable. But suppose that one has a field, $a$, with coupling to QCD:

$$\mathcal{L}_{\text{axion}} = (\partial_\mu a)^2 + \frac{(a/f_a + \theta)}{32\pi^2} F \tilde{F},$$  \hspace{1cm} (5.128)

where $f_a$ is known as the axion decay constant. Suppose, in addition, that the rest of the theory possesses a symmetry, called the Peccei–Quinn symmetry,

$$a \rightarrow a + \alpha$$  \hspace{1cm} (5.129)
for constant $\alpha$. Then, by a shift in $a$, one can eliminate $\theta$. What we previously called the vacuum energy as a function of $\theta$, $E(\theta)$, is now $V(a/f_a)$, the potential energy of the axion. It has a minimum at $\theta = 0$. The strong CP problem is solved.

One can estimate the axion mass by simply examining $E(\theta)$:

$$m_a^2 \approx \frac{m_{\pi}^2 f_{\pi}^2}{f_a^2}.$$  \hspace{1cm} (5.130)

If $f_a \sim \text{TeV}$, this yields a mass of order keV. If $f_a \sim 10^{16} \text{ GeV}$, this gives a mass of order $10^{-9} \text{ eV}$.

There are several questions one can raise about this proposal.

- Should the axion already have been observed? The couplings of the axion to matter can be worked out in a given model in a straightforward way, using the methods of current algebra (in particular of non-linear Lagrangians). All of the couplings of the axion are suppressed by powers of $f_a$. This is characteristic of a Goldstone boson. At zero momentum, a change in the field is like a symmetry transformation, so, before including the QCD effects which explicitly break the symmetry, axion couplings are suppressed by powers of momentum over $f_a$; QCD effects are suppressed by $\Lambda_{\text{QCD}}/f_a$. So if $f_a$ is large enough, the axion is difficult to see. The strongest limit turns out to come from red giant stars. The production of axions is “semiweak,” i.e. it only is suppressed by one power of $m_W$, rather than two powers of $m_W$; as a result, axion emission is competitive with neutrino emission until $f_a > 10^{10} \text{ GeV}$ or so.

- As we will describe in more detail in the chapters on cosmology, the axion can be copiously produced in the early universe. As a result, there is an upper bound on the axion decay constant, of about $10^{11} \text{ GeV}$. If this bound is saturated, the axion constitutes the dark matter. We will discuss this bound in detail in the chapter on particle astrophysics.

- Can one search for the axion experimentally? Typically, the axion couples not only to the $F \tilde{F}$ of QCD, but also to the same object in QED. This means that in a strong magnetic field, an axion can convert to a photon. Precisely this effect is being searched for by groups at Livermore (the collaboration contains members from MIT and the University of Florida as well) and Kyoto. The basic idea is to suppose that the dark matter in the halo of our galaxy consists principally of axions. Using a (superconducting) resonant cavity with a high $Q$ value in a large magnetic field, one searches for the conversion of these axions into excitations of the cavity, owing to the coupling of the axion to the electromagnetic $F \tilde{F} = \vec{E} \cdot \vec{B}$. The experiments have already reached a level where they set interesting limits; the next generation of experiments will cut a significant swath in the presently allowed parameter space.

- The coupling of the axion to $F \tilde{F}$ violates the shift symmetry; this is why the axion can develop a potential. But this seems rather paradoxical: one postulates a symmetry, preserved to some high degree of approximation, but which is not a symmetry; it is at least broken by tiny QCD effects. Is this reasonable? To understand the nature of the problem, consider one of the ways an axion can arise. In some approximation, we
5.5 Possible solutions of the strong CP problem

can suppose we have a global symmetry under which a scalar field, \( \phi \), transforms as \( \phi \rightarrow e^{i\alpha} \phi \). Suppose, further, that \( \phi \) has an expectation value. This could arise due to a potential, \( V(\phi) = -\mu^2|\phi|^2 + \lambda|\phi|^4 \). Associated with the symmetry breaking would be a (pseudo)-Goldstone boson, \( a \). We can parameterize \( \phi \) as:

\[
\phi = f_a e^{i a / f_a} \quad |\langle \phi \rangle| = f_a.
\]  

(5.131)

If this field couples to fermions, they gain mass from its expectation value. At one loop, the same diagrams we discussed in our anomaly analysis generate a coupling \( a F \tilde{F} \), from integrating out the fermions. This calculation is identical to the corresponding calculation for pions we discussed earlier. But we usually assume that global symmetries in nature are accidents. For example, baryon number is conserved in the standard model simply because there are no gauge-invariant, renormalizable operators which violate the symmetry. We believe it is violated by higher dimension terms. The global symmetry we postulate here is presumably an accident of the same sort. But for the axion, the symmetry must be extremely good. For example, suppose one has a symmetry breaking operator:

\[
\frac{\phi^{n+4}}{M_p^n}.
\]  

(5.132)

Such a term gives a linear contribution to the axion potential of order \( f_a^{n+3} / M_p^n \). If \( f_a \sim 10^{11} \), this swamps the would-be QCD contribution \( (m_\pi^2 f_\pi^2 / f_a) \) unless \( n > 12! \).

This last objection finds an answer in string theory. In this theory, there are axions, with just the right properties, i.e. there are symmetries in the theory which are exact in perturbation theory, but which are broken by exponentially small non-perturbative effects. The most natural value for \( f_a \) would appear to be of order \( M_{\text{GUT}} - M_p \). Whether this can be made compatible with cosmology, or whether one can obtain a lower scale, is an open question.

Suggested reading

There are a number of excellent books and reviews on anomalies, as well as good treatments in quantum field theory textbooks. The texts of Peskin and Schroeder (1995), Pokorski (2000) and Weinberg (1995) have excellent treatments of different aspects of anomalies. The string textbook of Green et al. (1987) provides a good introduction to anomalies in higher dimensions. One of the best introductions to the physics of instantons is provided in the lecture by Coleman (1985). The \( U(1) \) problem in two-dimensional electrodynamics, and its role as a model for confinement, is discussed by Casher et al. (1974). The serious reader should study ’t Hooft’s instanton paper from 1976, in which he both uncovers much of the physical significance of the instanton solution, and performs a detailed evaluation of the determinant. Propagators in the instanton background are obtained in Brown et al. (1978).
Instantons in CP\textsuperscript{N} models are studied by Affleck (1980). The dependence of \( d_n \) on \( \theta \) is calculated by Crewther \textit{et al.} (1979) in a short and quite readable paper.

\section*{Exercises}

(1) Derive Eq. (5.15).

(2) Calculate the decay rate of the \( \pi^0 \) to two photons. You will need the matrix element

\[ \langle \pi(q) | \partial_\mu J_5^{\mu3} | 0 \rangle = f_\pi q^\mu e^{iq\cdot x}, \]  

(5.133)

where \( f_\pi = 93 \text{ MeV} \). You will need also to compute the anomaly in the third component of the axial isospin current.

(3) Fill in the details of the anomaly computation in two dimensions, being careful about signs and factors of 2.

(4) Fill in the details of the Fujikawa computation of the anomaly, in the CP\textsuperscript{N} model, being careful about factors of 2. Make sure you understand why one is calculating a determinant, and why the factors appear in the exponential. Verify that the action of Eq. (5.56) is equal to

\[ \mathcal{L} = g_{\phi,\phi} \partial_\mu \phi \partial_\mu \phi^*, \]  

(5.134)

where \( g \) is the metric of the sphere in complex coordinates, i.e. it is the line element \( dx_1^2 + dx_2^2 + dx_3^2 \) expressed as \( g_{zz}dz\ dz^* + g_{zz}dz\ dz^* + g_{zz}dz\ dz^* + g_{dz\ dz^*}dz\ dz^* \). A model with an action of this form is called a “Non-linear Sigma Model;” the idea is that the fields live on some “target” space, with metric \( g \). Verify Eqs. (5.56) and (5.59).

(5) Check that Eqs. (5.86) and (5.87) solve (5.83).
One of the troubling features of the Standard Model is the plethora of coupling constants; overall, there are 18, counting \( \theta \). It seems puzzling that a theory which purports to be a fundamental theory should have so many parameters. Another is the puzzle of charge quantization: why are the hypercharges all rational multiplets of one another (and, as a result, the electric charges are rational multiples of one another)? Finally, the gauge group itself is rather puzzling. Why is it semi-simple and not simple?

Georgi and Glashow put forward a proposal which answers some of these questions. They suggested that the underlying gauge symmetry of nature is a simple group, broken at some high-energy scale down to the gauge group of the Standard Model. The Standard Model gauge group has rank 4 (there are four commuting generators). \( SU(N) \) groups have rank \( N - 1 \). So the simplest group among the \( SU(N) \)s which might incorporate the Standard Model is \( SU(5) \). Without any fancy group theory, it is easy to see how to embed \( SU(3) \times SU(2) \times U(1) \) in \( SU(5) \). Consider the gauge bosons. These are in the adjoint representation of the group. Written as matrices, under infinitesimal space-time independent gauge transformations,

\[
\delta A_\mu = i \omega^a [T^a, A_\mu]. \tag{6.1}
\]

The \( T_a \)s are \( 5 \times 5 \), traceless, Hermitian matrices; altogether, there are 24 of them. We can then break up the gauge generators in the following way. Writing the indices on \( T^a \) as \( (T^a)_i^j \), the \( T^a \)s act on the fundamental 5 representation as:

\[
(T^a)_i^j \cdot 5_j. \tag{6.2}
\]
Fig. 6.1. Exchange of heavy vector particles in GUTs violates B and L. They can lead to processes such as $p \rightarrow \pi^0 e^+$. 

So if we think of the 5 as:

$$5 = \begin{pmatrix} q_1 \\ q_2 \\ q_3 \\ L_1 \\ L_2 \end{pmatrix}$$

then the $T^a$s can be broken up into a set of $SU(3)$ generators and a set of $SU(2)$ generators:

$$T^a = \begin{pmatrix} \frac{\lambda^a}{2} \\ 0 \end{pmatrix} \quad T^i = \begin{pmatrix} 0 & 0 \\ 0 & \frac{\sigma^i}{2} \end{pmatrix}. \quad (6.4)$$

Here the $\lambda^a$s are Gell-Mann’s $SU(3)$ matrices, and the $\sigma^i$s are the Pauli matrices. There are three commuting matrices among these. The remaining diagonal matrix can be taken to be

$$\tilde{Y} = \frac{1}{\sqrt{60}} \begin{pmatrix} -2 & 0 & 0 & 0 & 0 \\ 0 & -2 & 0 & 0 & 0 \\ 0 & 0 & -2 & 0 & 0 \\ 0 & 0 & 0 & 3 & 0 \\ 0 & 0 & 0 & 0 & 3 \end{pmatrix}. \quad (6.5)$$

Finally, there are twelve off-diagonal matrices:

$$(X^i_a)_j^b = \delta^i_j \delta_a^b \quad (6.6)$$

where $a, b = 1, 2, 3; i, j = 1, 2$. These are not Hermitian; they are analogous to raising and lowering operators in $SU(2)$. One can readily form Hermitian linear combinations. The associated vector mesons must be very heavy; they mediate B-violating processes, as in Fig. 6.1. These can lead, for example, to $p \rightarrow \pi^0 e^+$. 
We want to claim that $\tilde{Y}$ is proportional to the ordinary hypercharge, and determine the proportionality constant. To do this, we consider, not the 5, but the $\bar{5}$, and identify:

$$\bar{5} = \begin{pmatrix} \bar{d}_1 \\ \bar{d}_2 \\ \bar{d}_3 \\ L_1 \\ L_2 \end{pmatrix}.$$  \hspace{1cm} (6.7)

Now the generators of $SU(5)$ acting on the $\bar{5}$ are $-T^{aT}$. So we can read off immediately that $Y = \sqrt{60} \tilde{Y} / 3$. Since the gauge groups are unified in a single group, the gauge couplings are all the same, so we can compute the Weinberg angle. Calling $g$ the $SU(5)$ coupling,

$$g \tilde{Y} = \frac{g'}{2} Y$$  \hspace{1cm} (6.8)

where $g'$ is the hypercharge coupling of the Standard Model. From this, $g^2 = 5/3 g'^2$. The Weinberg angle,

$$\sin^2(\theta_W) = \frac{g'^2}{g^2 + g'^2} = \frac{3}{8}. \hspace{1cm} (6.9)$$

So we have two dramatic predictions, if we assume that the Standard Model is unified in this way.

1. The $SU(3)$ and $SU(2)$ gauge couplings are equal.

Before assessing these predictions, let’s first figure out where we would put the rest of the quarks and leptons. In a single generation of the Standard Model, there are 15 fields. $SU(5)$ has a 10 representation, the antisymmetric product of two 5s. It can be written as an antisymmetric matrix, $10_{ij}$. If $i$ and $j$ are both $SU(3)$ indices, we obtain a $(\bar{3}, 1)_{-4/3}$ of $SU(3)$. If one is an $SU(3)$, one an $SU(2)$ index, we obtain a $(3, 2)_{1/3}$. If both are $SU(2)$ indices, we obtain a $(1, 1)_0$. Here the subscripts denote the ordinary hypercharge, related to $\tilde{Y}$ as above. These are just the quantum numbers of the $Q$, $\bar{u}$ and $\bar{e}$. As a matrix,

$$10 = \begin{pmatrix} 0 & \bar{u}^3 & -\bar{u}^2 & Q_1^1 & Q_1^2 \\ -\bar{u}^3 & 0 & \bar{u}^1 & Q_2^1 & Q_2^2 \\ \bar{u}^2 & -\bar{u}^1 & 0 & Q_3^1 & Q_3^2 \\ -Q_1^1 & -Q_2^1 & -Q_3^1 & 0 & \bar{e} \\ -Q_1^2 & -Q_2^2 & -Q_3^2 & -\bar{e} & 0 \end{pmatrix}. \hspace{1cm} (6.10)$$
6 Grand unification

So a single generation of quarks and leptons fits neatly into a 5 and 10 of SU(5).

6.1 Cancellation of anomalies

An anomaly in a gauge symmetry would represent a breakdown of gauge invariance. The consistency of gauge symmetries rests, however, on gauge invariance. For example, to demonstrate that the theories are both unitary and Lorentz invariant, we have used different gauges. Cancellation of anomalies is crucial, and the absence of anomalies in the Standard Model is surely no accident.

It is not hard to check that in SU(5), the anomaly of the 5 cancels that of the 10. In general, the anomalies in a gauge theory are proportional to $d_{abc}$, where

$$\{T_a, T_b\} = d_{abc} T_c.$$  \hfill (6.11)

One can organize the anticommutator above in terms of the various types of generators, for example SU(3), SU(2), U(1), and the off-diagonal generators, which transform as $(3, 2)$ of SU(3) × SU(2), and check each class. We leave the details for the exercises.

6.2 Renormalization of couplings

If we are going to describe the Standard Model, SU(5) must break at some high-energy scale to SU(3) × SU(2) × U(1). Above this scale, the full SU(5) symmetry holds to a good approximation, and all couplings renormalize the same way. Below this scale, the couplings renormalize differently. We can write the equations for the renormalization of the three separate couplings:

$$\alpha_i^{-1}(\mu) = \alpha_{\text{gut}}^{-1}(M_{\text{gut}}) + \frac{b_i^0}{4\pi} \ln \left( \frac{\mu}{M_{\text{gut}}} \right).$$  \hfill (6.12)

We can calculate the beta functions at one loop starting with the usual formula:

$$b_0 = \frac{11}{3} C_A - \frac{4}{3} c_f^{(i)} N_f^{(i)} - \frac{1}{3} c_{\phi}^{(i)} N_{\phi}^{(i)},$$  \hfill (6.13)

where $N_f^{(i)}$ is the number of fermions in the $i$th representation; $N_{\phi}^{(i)}$ is the number of scalars. For SU(N), $C_A = N$, and for fermions or scalars in the fundamental representation, $c_f = c_{\phi} = 1/2$.

For SU(3) and SU(2) the beta-function coefficients, $b_i^0$, are readily computed. For the U(1), we need to remember the relative normalization we computed above:

$$b_0^2 = 181/6 \quad b_0^3 = 7 \quad b_0^1 = \frac{61}{15}.$$  \hfill (6.14)
We can run these equations backwards. The $SU(2)$ and $U(1)$ couplings are the best measured, so it makes sense to start with these, and run them up to the unification scale. This determines $\alpha_{\text{gut}}$ and $M_{\text{gut}}$. We can then predict the value of the $SU(3)$ coupling at, say, $M_Z$. One finds that the unification scale, $M_{\text{gut}}$, is about $10^{15} \text{ GeV}$, and $\alpha_3$ is off by about seven standard deviations. In the exercises, you will have the opportunity to perform this calculation in detail. We will see later that low-energy supersymmetry greatly improves this.

### 6.3 Breaking to $SU(3) \times SU(2) \times U(1)$

In $SU(5)$, it is relatively easy to introduce a set of Higgs fields which break the gauge symmetry down to $SU(3) \times SU(2) \times U(1)$. Consider a Hermitian scalar field, $\Phi$, in the adjoint representation. Writing $\Phi$ as a matrix, we have the transformation law:

$$\delta \Phi = \omega^a [T^a, \Phi]. \quad (6.15)$$

Suppose that the minimum of the $\Phi$ potential lies at a point where:

$$\Phi = v\tilde{Y}. \quad (6.16)$$

Then the $SU(3)$, $SU(2)$ and $U(1)$ generators all commute with $\langle \Phi \rangle$, but the $X$s do not.

Consider the most general $SU(5)$-invariant potential:

$$V = -m^2 \text{Tr} \Phi^2 + \lambda \text{Tr} \Phi^4 + \lambda' (\text{Tr} \Phi^2)^2. \quad (6.17)$$

One can find the minimum of this potential by first using an $SU(5)$ transformation to diagonalize $\Phi$,

$$\Phi = \text{diag}(a_1, a_2, a_3, a_4, a_5). \quad (6.18)$$

The potential is a function of the $a_i$s, which one wants to minimize subject to the constraint of vanishing trace. This can be done by using a Lagrange multiplier.

To establish that one has a local minimum of the form of Eq. (6.16), one can proceed more simply. Write the potential as a function of $v$:

$$V = -\frac{1}{2} \mu^2 v^2 + \frac{a \lambda}{4} + \frac{b \lambda'}{4} v^4 \quad (6.19)$$

where $a = 7/120$. Then the extremum with respect to $v$ is:

$$v = \frac{\mu}{\sqrt{a \lambda + b \lambda'}}. \quad (6.20)$$

To establish that this is a local minimum, we need to show that the eigenvalues of the scalar mass-squared matrix are all positive. We can investigate this...
by considering small fluctuations about the stationary point. This point preserves $SU(3) \times SU(2) \times U(1)$. Writing $\Phi = \langle \Phi \rangle + \delta \Phi$, $\delta \Phi$ can be decomposed under $SU(3) \times SU(2) \times U(1)$ as

$$
\delta \Phi = (1, 1) + (8, 1) + (1, 3) + (3, 2) + (\bar{3}, 2).
$$

(6.21)

This point is certainly stationary; because of the symmetry, only the $(1, 1)$ piece can appear linearly in the potential, and it is this piece whose minimum we have just found. To establish that the point is in fact a local minimum, one needs to show that the quadratic terms in the fluctuations are all positive. This is done in the exercises.

#### 6.4 $SU(2) \times U(1)$ breaking

In addition to the adjoint, it is necessary to include a 5 of Higgs, $H$, in order to break $SU(2) \times U(1)$ to the $U(1)$ of electromagnetism and to give mass to the quarks and leptons. $H$ has the form

$$
H = \begin{pmatrix} H_c \\ H_d \end{pmatrix},
$$

(6.22)

where $H_c$ is a color triplet of scalars and $H_d$ is the ordinary Higgs doublet. For $H$ one might be tempted to write a potential of the form

$$
V(H) = -\mu^2 |H|^2 + \lambda |H|^4.
$$

(6.23)

However, this leads to a number of difficulties. Perhaps most important, when included in the larger theory with the adjoint field, $\Phi$, this potential has too much symmetry; there is an extra $SU(5)$, which would lead to an assortment of unwanted Goldstone bosons. At the same time, the scale, $\mu$, must be of order the scale of electroweak symmetry breaking (as long as $\lambda$ is not too much larger than one). So the Higgs triplets will have masses of order the weak scale. But if the doublet couples to quarks and leptons, the triplet will have baryon and lepton number violating couplings to the quarks and leptons. So the triplet must be very massive.

Both problems can be solved if we couple $\Phi$ to $H$. The allowed couplings include:

$$
V_{\Phi-H} = \Gamma H^* \Phi H + \lambda' H^* H \text{Tr} \Phi^2 + \lambda'' H^* \Phi^2 H.
$$

(6.24)

If we carefully adjust the constants $\Gamma$, $\lambda'$, $\lambda''$ and $\mu^2$, we can arrange that the doublets are light and the triplets are heavy. For example, if we choose $\lambda = \lambda' = 0$, and $\mu^2 = -3(\Gamma/\sqrt{60})v - \epsilon$ then the Higgs doublets have mass-squared $-\epsilon$ in the Lagrangian, while the triplets have mass of order $M_{\text{gut}}$. This tuning of parameters, which must be performed in each order of perturbation theory, provides an explicit realization of the hierarchy problem.
Turning to fermion masses, we are led to an interesting realization: not only does grand unification make predictions for the gauge couplings, it can predict relations among fermion masses as well. $SU(5)$ permits the following couplings:

$$\mathcal{L}_y = y_1 \epsilon_{ijklm} H^i 10^{jk} 10^{lm} + y_2 H^* \bar{5}_j 10^{ij}.$$ \hfill (6.25)

Here the $y$s are matrices in the space of generations. When $H$ acquires an expectation value, it gives mass to the quarks and leptons. The first coupling gives mass to the up-type quarks. The second coupling gives mass to both the down-type quarks and the leptons. If we consider only the heaviest generation, we then have the tree level prediction:

$$m_b = m_\tau.$$ \hfill (6.26)

This “prediction” is off by a factor of 3, but like the prediction of the coupling constant, it is corrected by renormalization by roughly the observed amount. For the lightest quarks and leptons, the prediction fails. However, unlike the unification of gauge couplings, such predictions can be modified if there are additional Higgs fields in other representations. In addition, for the lightest fermions, higher-dimension operators, suppressed by powers of the Planck mass, can make significant contributions to masses. In supersymmetric grand unified theories, the ratio of the GUT scale to the Planck scale is about $10^{-2}$, whereas the lightest quarks and leptons have masses four orders of magnitude below the weak scale. We will postpone numerical study of these corrections, since the simplest $SU(5)$ theory does not correctly predict the values of the coupling constants. We will return to this subject when we discuss supersymmetric grand unified theories, which do successfully predict the observed values of the couplings.

### 6.5 Charge quantization and magnetic monopoles

While we must postpone success with the calculation of the unified couplings to our chapters on supersymmetry, we should pause and note two triumphs. First, we have a possible explanation for one of physics’ greatest mysteries: why is electric charge quantized? Here it is automatic; electric charge, an $SU(5)$ generator, is quantized, just as color and isospin are quantized.

But Dirac long ago offered another explanation of electric charge quantization: magnetic monopoles. He realized that consistency of quantum mechanics demands that even if a single monopole exists in the universe, electric charges must all be integer multiples of a fundamental charge. So we might suspect that magnetic monopoles are hidden somewhere in this story. Indeed they are; these topics are discussed in Chapter 7.
6.6 Proton decay

We have discussed the dimension-six operators which can arise in the Standard Model and violate baryon number. Exchanges of the $X$ bosons generate operators such as:

$$\frac{g^2}{M_X^2} Q \sigma_{\mu} \bar{u}^a Q \sigma^\mu \bar{e}^b.$$  \hspace{2cm} (6.27)

This leads to the decay $p \rightarrow \pi^0 e^+$. In this model, one predicts a proton lifetime of order $10^{28}$ years if $M_{\text{gut}} \approx 10^{15}$ GeV. The current limit on this decay mode is $5 \times 10^{33}$ years. We will discuss the situation in supersymmetric models later.

The realization that baryon number violation is likely in any more fundamental theory opens up a vista on a fundamental question about nature: why is there more matter than antimatter in the universe. If, at some very early time, there were equal amounts of matter and antimatter, then if baryon number is violated, one has the possibility of producing an excess. Other conditions must be satisfied as well; we will describe this in the chapter on cosmology.

6.7 Other groups

While $SU(5)$ may in some respects be the simplest group for unification, once one has set off in this direction, there are many possibilities. Perhaps the next simplest is unification in the group $O(10)$. As $O(10)$ has rank 5, there is one extra commuting generator; presumably this symmetry must be broken at some scale. But more interesting is the fact that a single generation fits neatly in an irreducible representation: the 16. The $O(10)$ has an $SU(5)$ subgroup, under which the 16 decomposes as a $10 + \bar{5} + 1$. The singlet has precisely the right Standard Model quantum numbers – none – to play the role of the right-handed neutrino in the seesaw mechanism.

We won’t thoroughly review the group theory of $O$ groups, but we can describe some of the important features. We will focus specifically on $O(10)$, but much of the discussion here is easily generalized to other groups. The generators of $O(10)$ are $10 \times 10$ antisymmetric matrices. There are 45 of these. We are particularly interested in how these transform under the Standard Model group. The embedding of the Standard Model in $SU(5)$, as we have learned, is very simple, so a useful way to proceed to understand $O(10)$ is to find its $SU(5)$ subgroup.

One way to think of $O(10)$ is as the group of rotations of ten-dimensional vectors. Call the components of such a vector $x^A$, $A = 1, \ldots, 10$. $SU(5)$ transformations are “rotations” of complex five-dimensional vectors, $z^I$. So define

$$z^1 = x^1 + ix^2 \quad z^2 = x^3 + ix^4 \quad z^3 = x^5 + ix^6$$  \hspace{2cm} (6.28)
6.7 Other groups

and so on. With this correspondence, it is easy to see that a subgroup of $O(10)$ transformations preserves the product $z \cdot z^{*}$. This is the $SU(5)$ subgroup of $O(10)$.

From our construction, it follows that the 10 of $O(10)$ transforms as a $5 + \bar{5}$ of $SU(5)$. We can determine the decomposition of the adjoint by writing:

$$A^{AB} = A^{ii} + A^{ij} + A^{i\bar{j}}.$$  \hspace{1cm} (6.29)

The labeling here is meant to indicate the types of complex indices the matrix $A$ can carry. The first term is just the 24 of $SU(5)$, plus an additional singlet. This singlet is associated with a $U(1)$ subgroup of $O(10)$, which rotates all of the objects with $i$-type indices by one phase, and all of those with $\bar{i}$ type indices by the opposite phase. Note that $A^{ij}$ is antisymmetric in its indices; in our study of $SU(5)$, we learned that this is the 10 representation. We can take it to carry charge 2 under the $U(1)$ subgroup. $A^{i\bar{j}}$, then, is the $\bar{10}$ representation, with charge $-2$. This accounts for all 45 fields.

But where is the 16? We are familiar, from our experience with ordinary rotations in 3 and (Euclidean 4) dimensions, as well as from the Lorentz group, with the fact that $O$ groups may have spinor representations. To construct these, we need to introduce the equivalent of Dirac gamma matrices, $\Gamma$, satisfying:

$$\{\Gamma^I, \Gamma^J\} = 2\delta^{IJ}. \hspace{1cm} (6.30)$$

It is not hard to construct explicit matrices which satisfy these anticommutation relations, but there is a simpler approach, which also makes the $SU(5)$ embedding clear. The anticommutation relations are similar to the relations for fermion creation and annihilation operators. So define:

$$a^1 = \frac{1}{2}(\Gamma^1 + i\Gamma^2) \quad a^2 = \frac{1}{2}(\Gamma^3 + i\Gamma^4) \hspace{1cm} (6.31)$$

and so on, and similarly for their complex conjugates. Note that the $a^i$'s form a 5 of $SU(5)$, with charge +1 under the $U(1)$. These operators satisfy the algebra:

$$\{a^i, a^{\bar{j}}\} = \delta^{ij}. \hspace{1cm} (6.32)$$

These are the anticommutation relations for five pairs of fermion creation–annihilation operators. We know how to construct the corresponding “states,” i.e. the representations of the algebra. We define a state, $\ket{0}$, annihilated by the $a^i$'s. Then there are five states created by $a^{\bar{i}}$ acting on this state:

$$\bar{5}_{-1} = a^{\bar{i}}\ket{0}. \hspace{1cm} (6.33)$$

The $\bar{5}$ indicates the $SU(5)$ representation; the subscript the $U(1)$ charge. We could now construct the states obtained with two creation operators, but let’s construct
the states built with an odd number:

\[ 10_{-3} = a^i a^j a^k |0\rangle \quad 1_{-5} = a^1 a^2 a^3 a^4 a^5 |0\rangle. \]  

(6.34)

We have indicated that the first representation transforms like a 10 of \( SU(5) \), while the second transforms like a singlet.

The states which involve even numbers of creation operators transform like a 5, a \( \overline{10} \), and a singlet. Why do we distinguish these two sets? Remember, the goal of this construction is to obtain \textit{irreducible} representations of the group \( O(10) \).

As for the Dirac theory, we can construct the symmetry generators from the Dirac matrices,

\[ S^{IJ} = \frac{i}{4} [\Gamma^I, \Gamma^J]. \]  

(6.35)

These, too, can be decomposed on the complex basis, like \( A^{I} \). But, as for the usual Dirac matrices, there is another \( \Gamma \) matrix we can construct, the analog of \( \Gamma^5, \Gamma^{11} \). This matrix anticommutes with all of the \( \Gamma \)'s, and thus the \( a^I \)'s. Thus the states with even numbers of creation operators are eigenstates with eigenvalue +1 under \( \Gamma^{11} \), while those with odd numbers are eigenstates with eigenvalue −1. Since \( \Gamma^{11} \) commutes with the symmetry generators, these two representations are irreducible.

A similar construction works for other groups. When we come to discuss string theories in ten dimensions, we will be especially interested in the representations of \( O(8) \). Here the same construction yields two representations, denoted by 8 and 8'.

The embedding of the states of the Standard Model in \( O(10) \) is clear, since we already know how to embed them in a \( \tilde{5} + 10 \) of \( SU(5) \). But what of the other state in the 16? This is a Standard Model singlet. We don’t have a candidate, as of yet, in the particle data book for this. But there are two observations we can make. First, the symmetries of the Standard Model do not forbid a mass for this particle. What does forbid a mass is the extra \( U(1) \). So if this symmetry is broken at very high energies, perhaps with the initial breaking of the gauge symmetry, this particle can gain a large mass. We will not explore the possible Higgs fields in \( O(10) \), but, as in \( SU(5) \), there are many possibilities, and the \( U(1) \) can readily be broken. Second, this particle has the right quantum numbers to couple to the left-handed neutrino of the Standard Model. So this particle can naturally lead to a “seesaw” neutrino mass. This mass might be expected to be of order some typical Yukawa coupling, squared, divided by the unification scale. It is also possible that this extra \( U(1) \) is broken at some lower scale, yielding a larger value for the neutrino mass.
Suggested reading

There are any number of good books and reviews on the subject of grand unification. The books by Ross (1984), Mohapatra (2003) and Ramond (1999) all treat the topics introduced in this chapter in great detail. The reader will find his or her interest increases after studying some aspects of supersymmetry.

Exercises

(1) Verify the cancellation of anomalies between the $\bar{5}$ and 10 representations of $SU(5)$.

(2) Establish the conditions that the solution of Eq. (6.16) is a local minimum of the potential.

(3) Perform the calculation of coupling unification in the $SU(5)$ model. Verify Eq. (6.14) for the $SU(3)$, $SU(2)$ and $U(1)$ beta functions. Start with the measured values of the $SU(2)$ and $U(1)$ couplings, being careful about the differing normalizations in the Standard Model and in $SU(5)$. Compute the value of the unification scale (the point where these two couplings are equal); then determine the value of $\alpha_3$ at $M_Z$. Compare with the value given by the Particle Data Group. You need only study the equations to one-loop order. In practice, two-loop corrections, as well as threshold effects and higher-order corrections to the beta function, are often included.

(4) Add to the Higgs sector of the $SU(5)$ theory a set of scalars in the 45 representation. Show that in this case all of the quark masses are free parameters.
Magnetic monopoles and solitons

Anyone who has stared even briefly at Maxwell’s equations has speculated about the existence of magnetic monopoles. There is no experimental evidence for magnetic monopoles, but the equations would be far more symmetric if they existed. It was Dirac who first considered carefully the implications of monopoles, and he came to a striking conclusion: the existence of monopoles would require that electric charge be quantized in terms of a fundamental unit. The problem of describing a monopole lies in writing $\vec{B} = \vec{\nabla} \times \vec{A}$. We could simply give up this identification, but Dirac recognized that $\vec{A}$ is essential in formulating quantum mechanics. To resolve the problem, we can follow Wu and Yang, and maintain $\vec{B} = \vec{\nabla} \times \vec{A}$, but not require that the vector potential be single valued. Suppose we have a monopole located at the origin. In the northern hemisphere, we can take

$$A_N = \frac{g}{4\pi r} \frac{(1 - \cos(\theta))}{\sin(\theta)} \hat{e}_\phi, \quad (7.1)$$

while in the southern hemisphere we can take:

$$A_S = -\frac{g}{4\pi r} \frac{(1 + \cos(\theta))}{\sin(\theta)} \hat{e}_\phi. \quad (7.2)$$

By looking up the formulae for the curl in spherical coordinates, you can check that, in both hemispheres:

$$\vec{B} = \frac{g}{4\pi r^2} \hat{r}, \quad (7.3)$$

so indeed this does describe a magnetic monopole.

Each of these expressions is singular along a half-line: $A_N$ is singular along $\theta = \pi$; $A_S$ is singular along $\theta = 0$. These string-like singularities are known as Dirac strings. They are suitable vector potentials to describe infinitely long, thin solenoids, starting at the origin and going to infinity on the negative or positive $z$ axis. With a discontinuous $\vec{A}$, though, we need to ask whether quantum mechanics
is consistent. Consider the equator ($\theta = \pi/2$). Here

$$\vec{A}_N - \vec{A}_S = \frac{g}{2\pi r} \hat{e}_\phi = -\vec{\nabla} \chi \quad \chi = -\frac{g}{2\pi} \phi.$$  \hspace{1cm} (7.4)

So the difference has the form of a gauge transformation. But to be a gauge transformation, it must act sensibly on particles of definite charge. In particular, it must be single valued. As the particle circumnavigates the sphere, its wave function acquires a phase

$$e^{ie \int d\vec{x} \cdot \vec{A}}.$$  \hspace{1cm} (7.5)

Potentially, this phase is different if we use $\vec{A}_N$ or $\vec{A}_S$, in which case the string is a detectable, real object. But the phases are the same if

$$\exp \left( i \frac{eg}{2\pi} \oint d\vec{x} \cdot \vec{\nabla} \phi \right) = 1 \quad \text{or} \quad eg = 2\pi n.$$  \hspace{1cm} (7.6)

This is known as the Dirac quantization condition. Dirac argued that since $e$ can be the charge of any charged particle, if there is even one monopole somewhere in the universe, this result shows that charge must be quantized.

In pure electrodynamics, the status of magnetic monopoles is obscure; the $\vec{B}$ field is singular and the energy is infinite. But in non-Abelian gauge theories with scalar fields (Higgs fields), monopoles often arise as finite-energy, non-dissipative solutions of the classical equations. Such solutions cannot arise in linear theories, like electrodynamics; all configurations in such a theory spread with time. Non-dissipative solutions can only arise in non-linear theories, and even then, such solutions – known as solitons – can only arise in special circumstances.

The simplest theory which exhibits monopole solutions is $SU(2)$ (more precisely $O(3)$) Yang–Mills theory with a single Higgs particle in the adjoint representation. But before considering this case, which is somewhat complicated, it is helpful to consider solitons in lower-dimensional situations.

### 7.1 Solitons in $1 + 1$ dimensions

Consider a quantum field theory in $1 + 1$ dimension, with

$$\mathcal{L} = \frac{1}{2} (\partial_\mu \phi)^2 - V(\phi).$$  \hspace{1cm} (7.7)

Here

$$V(\phi) = -\frac{1}{2} m^2 \phi^2 + \lambda \phi^4.$$  \hspace{1cm} (7.8)
This potential, which is symmetric under $\phi \rightarrow -\phi$, has two degenerate minima, $\pm \phi_0$. Normally, we would choose as our vacuum a state localized about one or the other minimum. These correspond to trivial solutions of the equations of motion. But we can consider a more interesting solution, for which

$$\phi(x \rightarrow \pm \infty) \rightarrow \pm \phi_0.$$  

Such a solution interpolates between the two different vacua. We can construct this solution much as one solves analogous problems in classical mechanics, by quadrature. Finding the solution, known as the kink, is left for the exercises; the result is

$$\phi_{\text{kink}} = \phi_0 \tanh((x - x_0)m).$$

This solution is shown in Fig. 7.1. This object has finite energy. As we have indicated, there are a continuous infinity of solutions, corresponding to the fact that this kink can be located anywhere; this is a consequence of the underlying translational invariance. We can use this to understand in what sense the kink is a particle. Consider configurations which are not quite solutions of the equations of motion, in which $x_0$ is allowed to be a slowly varying function of $t$, $x_0(t)$. We can write the action for these configurations:

$$S_{\text{kink}} = \int dt \int dx \left[ \frac{1}{2}(\partial_{\mu} \phi_{\text{kink}})^2 - V(\phi_{\text{kink}}) \right].$$

Only the $\dot{\phi}$ term contributes. The result is:

$$S_{\text{kink}} = \int dt \frac{M}{2} \dot{x}_0^2.$$ 

Here $M$ is precisely the energy of the kink. So the kink truly acts as a particle. The $x_0$ is called a collective coordinate. We will see that such collective coordinates arise for each symmetry broken by the soliton. These are similar to the collective coordinates we encountered in the Euclidean problem of the instanton.
As we go up in dimension, the possible solitons become more interesting. Consider a $U(1)$ gauge theory in $2 + 1$ dimensions, with a single charged scalar field, $\phi$. This model is often called the Abelian Higgs model. The Lagrangian is:

$$L = |D_\mu \phi|^2 - V(|\phi|).$$  \hspace{1cm} (7.13)

We assume that the potential is such that

$$\langle \phi \rangle = v.$$  \hspace{1cm} (7.14)

Now we have a possibility we haven’t considered before. Working in plane polar coordinates, if we consider only the potential, we can imagine obtaining finite-energy configurations for which, at large $r$,

$$\phi \to e^{in\theta} v.$$  \hspace{1cm} (7.15)

Because the potential tends to its minimum at infinity, such a configuration has finite potential energy. However, the kinetic energy diverges since $\partial_\mu \phi$ includes $(1/r) \partial_\theta \phi$. We can try to cancel this with a non-vanishing gauge field. At $\infty$, the scalar field is a gauge transformation of the constant configuration, so to achieve finite energy we want to gauge transform the gauge field as well:

$$A_\theta \to n$$  \hspace{1cm} (7.16)

so $D_\mu \phi \to 1/r^2$, or faster. It is not hard to construct such solutions numerically. As for the kinks, these configurations have collective coordinates, corresponding to the two translational degrees of freedom and a rotational (or charge) degree of freedom.

We can take these configurations as configurations in a $3 + 1$-dimensional theory, which are constant with respect to $z$. Viewed in this way, these are vortices, or strings. One has collective coordinates corresponding to transverse motions of the string, $x_0(z, t)$, $y_0(z, t)$. These string configurations could be quite important in cosmology. Such a broken $U(1)$ theory could lead to the appearance of long strings, which could carry enormous amounts of energy. For a time, these were considered a possible origin of inhomogeneities leading to formation of galaxies, but the data now disfavors this possibility.

### 7.3 Magnetic monopoles

Dirac’s argument shows that, in the presence of a monopole, electric charges are all multiples of a basic charge. This means that the $U(1)$ is effectively compact. So a natural place to look for monopoles is in gauge theories where the $U(1)$ is a
subgroup of a simple group. The $SU(5)$ grand unified theory was an example of this type, where electric charge is quantized.

We start, though, with the simplest example of this sort, an $SU(2)$ gauge theory with Higgs fields in the adjoint representation, $\phi^a$. Such a theory was first considered by Georgi and Glashow as a model for weak interactions without neutral currents, and is known as the Georgi–Glashow model. An expectation value for $\phi$, $\phi^3 = v$, or

$$\phi = \frac{v}{2} \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix},$$

leaves an unbroken $U(1)$. The spectrum includes massive charged gauge bosons, $W^\pm$, and a massless gauge boson, which we will call the photon, $\gamma$. By analogy to the string/vortex solutions, we look for finite-energy at $\infty$

$$\phi \rightarrow g v.$$ 

In the $2 + 1$-dimensional case, we could think of the gauge transformation as a mapping from the space at infinity (topologically a circle) onto the gauge group (also a circle). In three dimensions, we want gauge transformations which map the two sphere, $S_2$, into the gauge group $SU(2)$. For example, we can take

$$g(\vec{x}) = i \hat{x}^i \sigma^i.$$ 

This suggests an “Ansatz” (guess) for a solution:

$$\phi^a = \hat{r}^a h(r) \quad A^a_i = -\epsilon^{aij} \hat{r}^j j(r).$$ 

This solution is very symmetric: it is invariant under a combined rotation in spin and isospin (rather similar to the sorts of symmetries of the instanton solution). Note that $h$ and $j$ satisfy coupled, non-linear equations, which, in general, must be solved numerically. We can see from the form of the action that the mass is of order $1/g^2$. In the next section we show that an analytic solution can be obtained in a particular limit.

We can write an elegant expression for the number of times $g(x)$ maps the sphere into the gauge group:

$$N = \frac{1}{4\pi} \int dS^i \epsilon_{ijk} \text{Tr}(g \partial_j g \partial_k g).$$

In terms of the field, $\phi$,

$$N = \frac{1}{8\pi v^3} \int \epsilon^{ijk} \epsilon^{abc} \partial_i \phi^a \partial_j \phi^b \partial_k \phi^c.$$
Finally, we need a definition of the magnetic charge. A natural choice is

$$\int d^3x \frac{1}{v} \partial_i (\phi^a B_i^a) = \frac{4\pi N}{e}.$$  

Putting these statements together, we see that this solution, the 't Hooft–Polyakov monopole, has one Dirac unit of magnetic charge.

### 7.4 The BPS limit

Prasad and Sommerfield wrote down an exact monopole solution in the limit that $V = 0$. This limit seemed, originally, rather artificial, but we will see later that some supersymmetric field theories automatically have vanishing potential for a subset of fields. What simplifies the analysis in this limit is that the equations for the monopole, which are ordinarily second-order non-linear differential equations, become first-order equations. We will shortly understand this by thinking about supersymmetry. But first, we can derive this by looking directly at the potential for the gauge and scalar fields. We start by deriving a bound, the BPS bound, on the mass of a static field configuration. Again, we call the gauge coupling $e$, to avoid confusion with the magnetic charge $g$:

$$M_m = \int d^3x \frac{1}{2} \left[ \frac{1}{e^2} \vec{B}^a \cdot \vec{B}^a + (\vec{D}\Phi)^a \cdot (\vec{D}\Phi)^a \right].$$  \hspace{1cm} (7.23)

We can compare this with

$$A_{\pm} = \int d^3x \left[ \frac{1}{e} \vec{B}^a \pm (\vec{D}\Phi)^a \right]^2 = \frac{1}{2} \int d^3x \left[ \frac{1}{e^2} \vec{B}^a{}^2 + (\vec{D}\Phi)^a{}^2 \right] \pm \int d^3x \frac{1}{e} \vec{B}^a (\vec{D}\Phi)^a. \hspace{1cm} (7.24)$$

In the last term, we can integrate by parts. You can check that this works for both parts of the covariant derivative, i.e. this term becomes:

$$\frac{1}{e} \int d^3x (\vec{D} \cdot \vec{B})^a \Phi^a \pm \frac{1}{e} \int d^2 \alpha \Phi^a \hat{n} \cdot \vec{B}^a. \hspace{1cm} (7.25)$$

The first term vanishes by the Bianchi identity (the Yang–Mills generalization of the equation $\vec{\nabla} \cdot \vec{B} = 0$). The second term is $v$ times what we have defined to be the monopole charge, $g$. So we have:

$$A_{\pm} = \int d^3x \left[ \frac{1}{e^2} \vec{B}^a \pm (\vec{D}\Phi)^a \right]^2 = M_m \pm \frac{vg}{e}. \hspace{1cm} (7.26)$$
The left-hand side of this equation is clearly greater than zero, so we have shown that

\[ M_m \geq \left| \frac{v g}{e} \right|. \] (7.27)

This bound, known as the Bogomolny or BPS bound, is saturated when

\[ \vec{B}^a = \pm \frac{1}{e} (\bar{D} \Phi)^a. \] (7.28)

Note that, while we have spoken so far throughout this chapter about SU(2), this result generalizes to any gauge group, with Higgs in the adjoint representation. But let’s focus on SU(2), and try to find a solution which satisfies the Bogomolny bound. As in the case of the ’t Hooft–Polyakov monopole, it is convenient to write:

\[ \Phi^a = \frac{\hat{p}^a}{er} H(evr) \quad A_i^a = -\epsilon_{ij} \frac{\hat{p}^j}{er} (1 - K(evr)). \] (7.29)

Here we are using a dimensionless variable, \( u = evr \), in terms of which the Hamiltonian scales simply. We are looking for solutions for which \( H \to 0 \) and \( K \to 1 \) as \( r \to 0 \). Otherwise, the solutions will be singular at the origin. At \( \infty \), we want the configuration to look like a gauge transformation of the vacuum solution, so

\[ K \to 0 \quad H \to evr \quad as \quad r \to \infty. \] (7.30)

We will leave the details to the exercises, but it is straightforward to show that these equations are solved by:

\[ H(y) = y \coth(y) - 1 \quad K(y) = \frac{y}{\sinh(y)}. \] (7.31)

The monopole mass is

\[ M_m = \frac{v g}{e} = \frac{2\pi v}{e^2}, \] (7.32)

as predicted by the BPS formula.

### 7.5 Collective coordinates for the monopole solution

In lower-dimensional examples, we witnessed the emergence of collective coordinates, which described the translations and other collective motions of the solitons. In the case of the monopole, we have similar collective coordinates. Again, the solutions violate translational invariance. As a result, we can generate new solutions by replacing \( \vec{x} \) by \( \vec{x} - \vec{x}_0 \). Now viewing \( x_0 \) as a slowly varying function of \( t \), we obtain, as before, the action of a particle of mass \( M_m \).
There is another collective coordinate of the monopole solution, which has quite remarkably properties. In the monopole solution, charged fields are excited. So the monopole solution is not invariant under the $U(1)$ gauge transformations of electrodynamics. One might think that this is not important; after all, we have stressed that gauge transformations are not real symmetries, but instead represent a redundancy of the description of a system. But we need to be more precise. In interpreting Yang–Mills instantons, we worked in $A_0 = 0$ gauge. In this gauge, the important gauge transformations are time-independent gauge transformations, and these fall into two classes: large gauge transformations and small gauge transformations. The small gauge transformations are those which fall rapidly to zero at infinity, and physical states must be invariant under these. For large gauge transformations, this is not the case, and they can correspond to physically distinct configurations.

For the monopole configurations, the interesting gauge transformations are those which tend, at infinity, to a transformation in the unbroken $U(1)$ direction. For large $r$, this direction is determined by the direction of the Higgs fields. We must be careful about gauge fixing, so again we work in $A_0 = 0$ gauge. For our collective motion, we want to study gauge transformations in this direction, which vary slowly in time. It is important, however, that we remain in $A_0 = 0$ gauge, so the transformations we will study are not quite gauge transformations. Specifically, we consider

$$\delta A_i = D_i \chi(t) \Phi / v,$$

(7.33)

but we transform $A_0$ by

$$\delta A_0 = D_0(\chi \Phi) / v - \dot{\chi} \Phi / v$$

(7.34)

and, in order that the Gauss law constraint be satisfied, $\delta \Phi = 0$. The action for $\chi$ has the form:

$$S = \frac{C}{2e^2} \dot{\chi}^2.$$  

(7.35)

Note that $\chi$ is bounded between 0 and $2\pi$, i.e. it is an angular variable. Its conjugate variable is like an angular momentum; calling this $Q$, we have

$$Q = p_{\chi} = \frac{C}{e^2} \dot{\chi}, \quad H = \frac{1}{2C} e^2 Q^2.$$  

(7.36)

In the case of a BPS monopole, the constant $C$ is $e^2 M_m / (2v^2)$. So each monopole has a tower of charged excitations, with energies of order $e^2$ above the ground state. These excitations of the monopole about the ground state are known as dyons. The mass formula for these states has the form, in the case of a BPS monopole:

$$M = vg + vQ^2 / g.$$  

(7.37)
We will understand this better when we embed this structure in a supersymmetric field theory.

### 7.6 The Witten effect: the electric charge in the presence of \( \theta \)

We have argued that in a \( U(1) \) gauge theory, it is difficult to see the effects of \( \theta \). But in the presence of a monopole, a \( \theta \) term has a dramatic effect, pointed out by Witten: the monopole acquires an electric charge, proportional to \( \theta \).

We can see this first in a heuristic way. We work in a gauge with non-zero \( A_0 \), and take all fields static. Then

\[
\vec{E} = -\vec{\nabla} A_0 \quad \vec{B} = \frac{g}{4\pi} \frac{\vec{r}}{r^2} + \vec{\nabla} \times \vec{A}.
\]  

(7.38)

For such a configuration, the \( \theta \) term,

\[
\mathcal{L}_\theta = \frac{\theta e^2}{8\pi^2} \vec{E} \cdot \vec{B}
\]  

(7.39)

takes the form

\[
\mathcal{L}_\theta = -\frac{\theta e^2 g}{32\pi^2} \int d^3r A_0 \vec{\nabla} \cdot \frac{\vec{r}}{r^2} = -\frac{\theta e^2 g}{8\pi^2} \int d^3r A_0 \delta(\vec{r}).
\]  

(7.40)

We started with a magnetic monopole at the origin, but we now also have an electric charge at the origin, \( (\theta e^2 g)/(8\pi^2) \).

One might worry that in this analysis one is dealing with a singular field configuration, and in the non-Abelian case the configuration is non-singular. We can give a more precise argument. Let’s go back to \( A_0 = 0 \) gauge. In this gauge, we can sensibly write down the canonical Hamiltonian. In the absence of \( \theta \), the conjugate momentum to \( \vec{A} \) is \( \vec{E} \). But in the presence of \( \theta \), there is an additional contribution:

\[
\dot{\vec{\Pi}} = -\frac{d\vec{A}}{dt} + \frac{\theta e^2}{8\pi^2} \vec{B}.
\]  

(7.41)

Now let’s think about the invariance of states under small gauge transformations. For \( \theta = 0 \), we saw that the small gauge transformations, with gauge parameter \( \omega \), are generated by

\[
Q_\omega = \int d^3x \vec{\nabla} \omega \cdot \vec{E}.
\]  

(7.42)

An interesting set of large gauge transformations are those with \( \omega^a = \lambda \Phi^a/v \). For these, if we integrate by parts, we obtain a term which vanishes by Gauss’s law (Gauss’s law is enforced by the invariance under small gauge transformations), and a surface term. This surface term gives the total \( U(1) \) charge times \( \lambda \). But we can think of this another way. For the low-lying excitations, multiplication by \( e^{iQ_\omega} \).
is like shifting the dynamical variable $\chi$ by a constant, $\lambda$. In general, the wave functions for $\chi$ have the form $e^{iq\chi}$, where $q$ is quantized. So the states pick up a phase $e^{iq\lambda}$. This is just the transformation of a state of charge $q$ under the global gauge transformation with phase $\lambda$.

In the presence of $\theta$, however, the operator which implements time-independent gauge transformations is modified. The $\vec{E}$ is replaced by the canonical momentum above. Now acting on states, the extra piece gives a factor $(g\theta)/(2\pi)$ in the exponent. Even states with $q = 0$ now pick up a phase, so there is an additional contribution to the charge:

$$ Q = n_e e - \frac{\theta n_m}{2\pi}. \quad (7.43) $$

### 7.7 Electric–magnetic duality

Anyone who has ever seen Maxwell’s equations has speculated on a possible duality between electricity and magnetism. If there were magnetic charges, these equations would take the form:

$$ \vec{\nabla} \cdot \vec{E} = \rho_e \quad \vec{\nabla} \cdot \vec{B} = \rho_m, $$

$$ \vec{\nabla} \times \vec{E} = -\frac{\partial \vec{B}}{\partial t} + \vec{j}_m \quad \vec{\nabla} \times \vec{B} = \frac{\partial \vec{E}}{\partial t} + \vec{j}_e. \quad (7.45) $$

These equations retain their form if we, replace $\vec{E} \rightarrow -\vec{B}$, $\vec{B} \rightarrow \vec{E}$ and also let $\rho_e \rightarrow \rho_m$, $\rho_m \rightarrow -\rho_e$ (and similarly for the electric and magnetic currents).

Now that we have a framework for discussing magnetic charges, it is natural to ask whether some theories of electrodynamics really obey such a symmetry. In general, however, this is a difficult problem. We have just learned that electric and magnetic charges, when they both exist, obey a reciprocal relation, $g \propto 1/e$. From the point of view of quantum field theory, this means that exchanging electric and magnetic charges also means replacing the fundamental coupling by its inverse. In other words, if there is such a duality symmetry, it relates a strongly coupled theory to a weakly coupled theory. We don’t know a great deal about strongly coupled gauge theories, so investigating the possibility of such a duality is a difficult problem. That such a symmetry might exist in theories of the type we have been discussing is not entirely crazy. For example, the monopole masses behave, at weak coupling, like $1/g^2$. So as the coupling becomes strong, these particles become light, even as the charged states become heavy. They have complicated quantum numbers (some of the monopole states are fermionic, for example).

Remarkably, there is a circumstance where such dualities can be studied: theories with more than one supersymmetry (in four dimensions). $N = 4$ supersymmetric
Yang–Mills theory turns out to exhibit an electric–magnetic duality. These theories will be discussed in Chapter 15. Crucial to verifying this duality will be a deeper understanding of the BPS condition, which will allow us to establish exact formulas for masses of certain particles, valid for all values of the coupling. These formulas will exhibit precisely the expected duality between electricity and magnetism.

**Suggested reading**

There are many excellent reviews and texts on monopoles. These include Coleman (1981) and Harvey (1996), and this chapter borrows ideas from both. You can find an introduction to the subject in Chapter 6 of Jackson’s electrodynamics text (1999).

**Exercises**

1. Verify that Eqs. (7.1) and (7.2) are those of infinitely long, thin solenoids ending at the origin.

2. Find the kink solution of the 1 + 1-dimensional model. Show that the collective coordinate action is

   \[ S = \int dt \frac{1}{2} M_{\text{kink}} \dot{x}^2. \]

3. Verify that Eq. (7.31) solves the BPS equations.
8

Technicolor: a first attempt to explain hierarchies

In Chapter 5, we learned a great deal about the dynamics of quantum chromodynamics. In Section 4.5, we argued that the hierarchy problem is one of the puzzles of the Standard Model. The grand unified models of the previous chapter provided a quite stark realization of the hierarchy problem. In an $SU(5)$ grand unified model, we saw that it is necessary to carefully adjust the couplings in the Higgs potential in order that one obtain light doublets and heavy color triplet Higgs. This is already true at tree level; loop effects will correct these relations, requiring further delicate adjustments.

The first proposal to resolve this problem goes by the name “technicolor” and is the subject of this chapter. The technicolor hypothesis exploits our understanding of QCD dynamics. It elegantly explains the breaking of the electroweak symmetry. It has more difficulty accounting for the masses of the quarks and leptons, and simple versions seem incompatible with precision studies of the $W$ and $Z$ particles. In this chapter, we will introduce the basic features of the technicolor hypothesis. We will not attempt to review the many models that have been developed to try to address the difficulties of flavor and precision electroweak experiments. It is probably safe to say that, as of this writing, none is totally successful, nor are they terribly plausible. But it should be kept in mind that this may reflect the limitations of theorists; experiment may yet reveal that nature has chosen this path. In the second part of this book, we will argue that in string theory, ignoring phenomenological details, a technicolored solution to the hierarchy problem seems as likely as its main competitor, supersymmetry. Perhaps some reader of this book will realize what theorists have been missing.

Apart from the fact that technicolor might have something to do with Nature, this brief chapter will also provide an opportunity to develop a deeper understanding of the non-perturbative aspects of gauge theories.
8.1 QCD in a world without Higgs fields

Consider a world with only a single generation of quarks and no Higgs fields. In such a world, the quarks would be exactly massless. The $SU(2)_L \times SU(2)_R$ symmetry of QCD would be, in part, a gauge symmetry. $SU(2)_L$ would correspond to the $SU(2)$ symmetry of the weak interactions. Hypercharge, $Y$, would include a generator of $SU(2)_R$ and baryon number:

$$Y = 2T_{3R} + B.$$  \hspace{1cm} (8.1)

The quark condensate,

$$\langle q_f \bar{q}_{f'} \rangle = \Lambda^3 \delta_{ff'},$$  \hspace{1cm} (8.2)

would break some of the gauge symmetry. Electric charge, however, would be conserved, so $SU(2) \times U(1) \rightarrow U(1)$.

In Appendix C, we saw that the quark condensate conserves a vector $SU(2)$, ordinary isospin. This $SU(2)$ is generated by the linear sum

$$T_i = T_{iL} + T_{iR}.$$  \hspace{1cm} (8.3)

So the $SU(2)$ gauge bosons transform as a triplet of the conserved isospin. This guarantees that the successful tree-level relation,

$$M_W = M_Z \cos(\theta),$$  \hspace{1cm} (8.4)

is satisfied.

To understand the masses of the gauge bosons, remember that for a broken symmetry with current $j^\mu$, the coupling of the Goldstone boson to the current is

$$\langle 0 | j^\mu | \pi(p) \rangle = i f_\pi p^\mu.$$  \hspace{1cm} (8.5)

This means that there is a non-zero amplitude for a gauge boson to turn into a Goldstone, and vice versa. The diagram of Fig. 8.1 is proportional to:

$$g^2 f_\pi^2 p^\mu \frac{i}{p^2} p^\nu.$$  \hspace{1cm} (8.6)

As the momentum tends to zero, this tends to a constant – the mass of the gauge boson. For the charged gauge bosons, the mass is just:

$$m_{W^\pm}^2 = g^2 f_\pi^2$$  \hspace{1cm} (8.7)
8.2 Fermion masses: extended technicolor

while for the neutral gauge bosons we have a mass matrix:

\[ f_\pi^2 \begin{pmatrix} g^2 & gg' \\ gg' & g'2 \end{pmatrix} \]  

(8.8)
giving one massless gauge boson and one with mass-squared \((g^2 + g'^2)f_\pi^2\).

All of this can be nicely described in terms of the non-linear sigma model which is used to describe pion physics. Recall that the pions could be described in terms of a matrix,

\[ \Sigma = |\langle \bar{\psi} \psi \rangle|e^{i\frac{\vec{\pi} \cdot \vec{\tau}}{2}}, \]  

(8.9)

which transforms under \(SU(2)_L \times SU(2)_R\) as:

\[ \Sigma \rightarrow U_L \Sigma U_R^\dagger. \]  

(8.10)

Changes in the magnitude of the condensate are associated with excitations in QCD much more massive than the pion fields (the \(\sigma\) field of our linear sigma model of Section 2.2). So it is natural to treat this as a constant. \(\Sigma\) is then a field constrained to move on a manifold. As in our examples in two dimensions, a model based on such a field is called a non-linear sigma model. The Lagrangian is:

\[ \mathcal{L} = f_\pi^2 \text{Tr} \partial_\mu \Sigma^\dagger \partial^\mu \Sigma. \]  

(8.11)

In the context of the physics of light pseudo-Goldstone particles, the virtue of such a model is it incorporates the effects of broken symmetry in a very simple way. For example, all of the results of current algebra can be derived by studying the physics of such a theory and its associated Lagrangian.

In the case of the \(\sigma\)-model, we have an identical structure, except that we have gauged some of the symmetry, so we need to replace the derivatives by covariant derivatives:

\[ \partial_\mu \Sigma \rightarrow D_\mu \Sigma = \partial_\mu \Sigma - i \frac{A^a_\mu \sigma_a}{2} \Sigma - i \Sigma \frac{\sigma_3}{2} B_\mu. \]  

(8.12)

Again, we can choose unitary gauge; we just set \(\Sigma = 1\). So the Lagrangian in this gauge is simply:

\[ \mathcal{L} = \text{Tr} \left( \frac{A^a_\mu \sigma_a}{2} \Sigma + \Sigma \frac{\sigma_3}{2} B_\mu \right)^2. \]  

(8.13)

This yields exactly the mass matrix we wrote before.

8.2 Fermion masses: extended technicolor

In technicolor models, the Higgs field is replaced by new strong interactions which break \(SU(2) \times U(1)\) at a scale \(F_\pi = 1\) TeV. But the Higgs field of the Standard
Model gives masses not only to the gauge bosons, but to the quarks and leptons as well. In the absence of the Higgs scalar, there are chiral symmetries which prohibit masses for any of the quarks and leptons. While our simple model can explain the masses of the $W$s and $Z$s, it has no mechanism to generate the masses for the ordinary quarks and leptons.

If we are not to introduce fundamental scalars, the only way to break these symmetries is to introduce further gauge interactions. Consider first a single generation of quarks and leptons. Enlarge the gauge group to $SU(3) \times SU(2) \times U(1) \times SU(N + 1)$. The technicolor group will be an $SU(N)$ subgroup of the last factor. Take each quark and lepton to be part of an $N + 1$ or $\overline{N + 1}$ of this larger group. To avoid anomalies, we will also include a right-handed neutrino. In other words, our multiplet structure is:

$$\begin{pmatrix} Q \\ q \\ \bar{U} \\ \bar{u} \\ \bar{D} \\ \bar{d} \\ L \\ \ell \\ \bar{E} \\ \bar{e} \\ \bar{N} \\ \bar{\nu} \end{pmatrix}. \tag{8.14}$$

Here $q, \bar{u}, \bar{d}, \ell, \text{etc.}$, are the usual quarks and leptons; the fields denoted with capital letters are the techniquarks. Now suppose that the $SU(N + 1)$ is broken to $SU(N)$ by some other gauge interactions, in a manner similar to technicolor, at a scale $\Lambda_{\text{tc}} \gg \Lambda_{\text{etc}}$. Then there are a set of broken gauge generators with mass of order $\Lambda_{\text{etc}}$. Exchanges of these bosons give rise to operators such as:

$$\mathcal{L}_{4f} = \frac{1}{\Lambda_{\text{etc}}^2} Q \sigma_\mu q^* \bar{U} \sigma^\mu \bar{u}^* + \text{h.c.} \tag{8.15}$$

Using the identity for the Pauli matrices,

$$\sum_\mu (\sigma_\mu)_{\alpha \dot{\alpha}} (\sigma^{\mu})^{\dot{\beta} \beta} = \delta^\beta_\alpha \delta^{\dot{\beta}}_{\dot{\alpha}}, \tag{8.16}$$

permits us to rewrite the four-fermi interaction:

$$\mathcal{L}_{4f} = \frac{1}{\Lambda_{\text{etc}}^3} Q \bar{U} q^* \bar{u}^* + \text{h.c.} \tag{8.17}$$

We can replace $Q \bar{U}$ by its expectation value, of order $\Lambda_{\text{tc}}^3$. This gives rise to a mass for the $u$ quark. The other quarks and leptons gain mass in a similar fashion.

This model is clearly unrealistic on many counts: it has only one generation; there is a massive neutrino; there are relations among the masses which are unrealistic; there are approximate global symmetries which lead to unwanted pseudo-Goldstone bosons. Still, it illustrates the basic idea of extended technicolor models: additional gauge interactions break the unwanted chiral symmetries which protect the quark and lepton masses.
One can try to build realistic models by considering more complicated groups and representations for the extended technicolor (etc) interactions. Rather than attempt this here, we consider some of the issues in a general way. We imagine we have a model with three generations. The extended technicolor interactions generate a set of four-Fermi interactions which break the chiral symmetries which act on the separate quarks and leptons. In a model of three generations, there are a number of challenges which must be addressed.

(1) Perhaps the most serious is the problem of flavor-changing neutral currents. In addition to four-Fermi operators which generate mass, there will also be four-Fermi operators involving just the ordinary quarks and leptons. These operators will not, in general, respect flavor symmetries. They are likely to include terms like

$$L_{\Delta S=2} = \frac{1}{\Lambda_{\text{etc}}} \bar{s}d^*s^*,$$

which violate strangeness by two units. Unless $\Lambda_{\text{etc}}$ is extremely large (of the order of hundreds of TeV), this will lead to unacceptably large rates for $K^0 \leftrightarrow \bar{K}^0$.

(2) Generating the top quark mass is potentially problematic. The top quark mass is larger than the $W$ and $Z$ masses. Yet if the ETC scale is large, it is hard to see how to achieve this.

(3) The problem of pseudo-Goldstone bosons is generic to technicolor models, in just the fashion we saw for the simple model.

The challenge of technicolor model building is to construct models which solve these problems. We will not attempt to review the various approaches which have been put forward here. Models which solve these problems are typically extremely complicated. Instead, we will close by briefly discussing another serious difficulty: precision measurements of electroweak processes.

### 8.3 Precision electroweak measurements

In Section 4.5, we stressed that the parameters of the electroweak theory have been measured with high precision, and compared with detailed theoretical calculations, including radiative corrections. One naturally might wonder whether a strongly interacting Higgs sector could reproduce these results. The answer is that it is difficult. There are two categories of corrections which one needs to consider. The first are, in essence, corrections to the relation

$$M_W = M_Z \cos(\theta_W).$$

In a general technicolor model, these will be large. But we have seen why this relation holds in the minimal Standard Model: there is an approximate, global
SU(2) symmetry. This is in fact the case of the simplest technicolor model we encountered above. So this problem likely has solutions.

There are, however, other corrections as well, resulting from the fact that in these strongly coupled theories, the gauge boson propagators are quite different than those of weakly coupled field theories. These have been estimated in many models, and are found to be far too large to be consistent with the data. More details about this problem, and speculations on possible solutions, can be found in the Suggested reading.

**Suggested reading**

An up-to-date set of lectures on technicolor, including the problems of flavor and electroweak precision measurements, are those of Chivukula. An introduction to the analysis of precision electroweak physics is provided by Peskin (1990); for the application to technicolor theories, see Peskin and Takeuchi (1990).

**Exercises**

1. Determine the relations between the quark and lepton masses in the extended technicolor model above.

2. What are the symmetries of the extended technicolor model in the limit that we turn off the ordinary $SU(3) \times SU(2) \times U(1)$ gauge interactions? How many of these symmetries are broken by the condensate? Each of these broken symmetries gives rise to an appropriate Nambu–Goldstone boson. Some of these approximate symmetries are broken explicitly by the ordinary gauge interactions. The corresponding Goldstone bosons will then gain mass, typically of order $\alpha_i \Lambda_{\text{etc}}$. But some will not gain mass of this order. Which symmetry (or symmetries) will be respected by the ordinary gauge interactions?
Part 2

Supersymmetry
In a standard advanced field theory course, one learns about a number of symmetries: Poincaré invariance, global continuous symmetries, discrete symmetries, gauge symmetries, approximate and exact symmetries. These latter symmetries all have the property that they commute with Lorentz transformations, and in particular they commute with rotations. So the multiplets of the symmetries always contain particles of the same spin; in particular, they always consist of either bosons or fermions.

For a long time, it was believed that these were the only allowed types of symmetry; this statement was even embodied in a theorem, known as the Coleman–Mandula theorem. However, physicists studying theories based on strings stumbled on a symmetry which related fields of different spin. Others quickly worked out simple field theories with this new symmetry: supersymmetry.

Supersymmetric field theories can be formulated in dimensions up to eleven. These higher-dimensional theories will be important when we consider string theory. In this chapter, we consider theories in four dimensions. The supersymmetry charges, because they change spin, must themselves carry spin – they are spin-1/2 operators. They transform as doublets under the Lorentz group, just like the two-component spinors $\chi$ and $\chi^*$. (The theory of two-component spinors is reviewed in Appendix A, where our notation, which is essentially that of the text by Wess and Bagger (1992), is explained). There can be 1, 2, 4 or 8 such spinors; correspondingly, the symmetry is said to be $N = 1, 2, 4$ or 8 supersymmetry. Like generators of an ordinary group, the supersymmetry generators obey an algebra; unlike an ordinary bosonic group, however, the algebra involves anticommutators as well as commutators (it is said to be “graded”).

There are at least four reasons to think that supersymmetry might have something to do with TeV-scale physics. The first is the hierarchy problem: as we will see, supersymmetry can both explain how hierarchies arise, and why there are not large radiative corrections. The second is the unification of couplings. We have seen that
while the gauge group of the Standard Model can rather naturally be unified in a larger group, the couplings do not unify properly. In the minimal supersymmetric extension of the Standard Model (the Minimal Supersymmetric Standard Model, or MSSM) the couplings unify nicely, if the scale of supersymmetry breaking is about 1 TeV. Third, the assumption of TeV-scale supersymmetry almost automatically yields a suitable candidate for the dark matter, with a density in the required range. Finally, low-energy supersymmetry is strongly suggested by string theory, though at present one cannot assert that this is a prediction.

9.1 The supersymmetry algebra and its representations

Because the supersymmetry generators are spinors, they do not commute with the Lorentz generators. Perhaps, then, it is not surprising that the supersymmetry algebra involves the translation generators ($\hat{Q}_\alpha$, $\hat{\bar{Q}}^{\dot{\alpha}}$):

$$\{Q^A_\alpha, \bar{Q}^B_{\dot{\alpha}}\} = 2\sigma_\mu^{\alpha\dot{\alpha}} \delta^{AB} P_\mu$$

(9.1)

$$\{Q^A_\alpha, \bar{Q}^B_{\dot{\alpha}}\} = \epsilon_{\alpha\dot{\alpha}} X_{AB}.$$  

(9.2)

The $X_{AB}$ are Lorentz scalars, antisymmetric in $A, B$, known as central charges.

If nature is supersymmetric, it is likely that the low-energy symmetry is $N = 1$, corresponding to only one possible value for the index $A$ above. Only $N = 1$ supersymmetry has chiral representations. Of course, one might imagine that the chiral matter would arise at the point where supersymmetry was broken. But, as we will see, it is very difficult to break $N > 1$ supersymmetry spontaneously; this is not the case for $N = 1$. The smallest irreducible representations of $N = 1$ supersymmetry which can describe massless fields are as follows.

- Chiral superfields: $(\phi, \psi_\alpha)$, a complex scalar and a chiral fermion.
- Vector superfields: $(\lambda, A_\mu)$, a chiral fermion and a vector meson, both, in general, in the adjoint representation of the gauge group.
- The gravity supermultiplet: $(\bar{\psi}_\mu, \bar{\alpha}, g_{\mu\nu})$, a spin-3/2 particle, the gravitino, and the graviton.

One can work in terms of these fields, writing supersymmetry transformation laws and constructing invariants. This turns out to be rather complicated. One must use the equations of motion to realize the full algebra. Great simplification is achieved by enlarging space-time to include commuting and anticommuting variables. The resulting space is called superspace.

9.2 Superspace

We may conveniently describe $N = 1$ supersymmetric field theories by using superspace. Superspace allows a simple description of the action of the symmetry on
9.2 Superspace

fields and provides an efficient algorithm for construction of invariant Lagrangians. In addition, calculations of Feynman graphs and other quantities are often greatly simplified using superspace, at least in the limit that supersymmetry is unbroken or nearly so.

In superspace, in addition to the ordinary coordinates, $x^\mu$, one has a set of anticommuting, Grassmann, coordinates, $\theta_\alpha, \bar{\theta}_\dot{\alpha}$. The Grassmann coordinates obey:

$$\{\theta_\alpha, \theta_\beta\} = \{\bar{\theta}_\dot{\alpha}, \bar{\theta}_\dot{\beta}\} = \{\theta_\alpha, \bar{\theta}_\dot{\beta}\} = 0.$$  (9.3)

Grassmann coordinates provide a representation of the classical configuration space for fermions; they are familiar from the problem of formulating the fermion functional integral. Note that the square of any $\theta$ vanishes. Derivatives also anticommute:

$$\left\{ \frac{\partial}{\partial \theta_\alpha}, \frac{\partial}{\partial \bar{\theta}_\dot{\beta}} \right\} = 0, \text{ etc.}$$  (9.4)

Crucial in the discussion of Grassmann variables is the problem of integration. In discussing Poincaré invariance of ordinary field theory Lagrangians, the property of ordinary integrals that

$$\int_{-\infty}^{\infty} df(x + a) = \int_{-\infty}^{\infty} df(x)$$  (9.5)

is important. We require that the analogous property hold for Grassmann integration (here for one variable):

$$\int d\theta f(\theta + \epsilon) = \int d\theta f(\theta).$$  (9.6)

This is satisfied by the integration rule:

$$\int d\theta (1, \theta) = (0, 1).$$  (9.7)

For the case of $\theta_\alpha, \bar{\theta}_\dot{\alpha}$, one can write a simple integral table:

$$\int d^2\theta \theta^2 = 1; \int d^2\bar{\theta} \bar{\theta}^2 = 1,$$  (9.8)

all others vanishing.

One can formulate a superspace description for both local and global supersymmetry. The local case is rather complicated, and we won’t deal with it here, referring the interested reader to the suggested reading, and confining our attention to the global case.

The goal of the superspace formulation is to provide a classical description of the action of the symmetry on fields, just as one describes the action of the
Supersymmetry Poincaré generators. Consider functions of the superspace variables, \( f(x^\mu, \theta, \bar{\theta}) \). The supersymmetry generators act on these as differential operators: \( x^\mu, \theta, \theta^* \):

\[
Q_\alpha = \frac{\partial}{\partial \theta^\alpha} - i \sigma^{\mu}_{\alpha \dot{\alpha}} \theta^{*\dot{\alpha}} \partial_{\mu}; \quad \bar{Q}_{\dot{\alpha}} = - \frac{\partial}{\partial \bar{\theta}^{\dot{\alpha}}} + i \theta^{*\alpha} \sigma^{\mu}_{\alpha\dot{\alpha}} \partial_{\mu}.
\] (9.9)

Note that the \( \theta \)s have mass dimension \(-1/2\). It is easy to check that the \( Q_\alpha \)s obey the algebra. For example,

\[
\{Q_\alpha, Q_\beta\} = \left\{ \left( \frac{\partial}{\partial \theta^\alpha} - i \sigma^{\mu}_{\alpha \dot{\alpha}} \theta^{*\dot{\alpha}} \partial_{\mu} \right), \left( \frac{\partial}{\partial \theta^\beta} - i \sigma^{\nu}_{\beta \dot{\beta}} \theta^{*\dot{\beta}} \partial_{\nu} \right) \right\} = 0,
\] (9.10)

since the \( \theta \)s and their derivatives anticommute. With just slightly more effort, one can construct the \( \{Q_\alpha, Q^*_{\dot{\alpha}}\} \) anticommutator.

One can think of the \( Q \)s as generating infinitesimal transformations in superspace with Grassmann parameter \( \epsilon \). One can construct finite transformations as well by exponentiating the \( Q \)s; because there are only a finite number of non-vanishing polynomials in the \( \theta \)s, these exponentials contain only a finite number of terms. The result can be expressed elegantly:

\[
e^{\epsilon Q + \epsilon^* \bar{Q}} \Phi(x^\mu, \theta, \bar{\theta}) = \Phi(x^\mu - i \epsilon \sigma^\mu \theta^* + i \theta \sigma^\mu \epsilon^* + \theta + \epsilon, \bar{\theta} + \epsilon^*). \] (9.11)

If one expands \( \Phi \) in powers of \( \theta \), there are only a finite number of terms. These can be decomposed into two irreducible representations of the algebra, corresponding to the chiral and vector superfields described above. To understand these, we need to introduce one more set of objects, the covariant derivatives, \( D_\alpha \) and \( \bar{D}_{\dot{\alpha}} \). These are objects which anticommute with the supersymmetry generators, and thus are useful for writing down invariant expressions. They are given by

\[
D_\alpha = \partial_\alpha + i \sigma^\mu_{\alpha \dot{\alpha}} \theta^{*\dot{\alpha}} \partial_{\mu}; \quad \bar{D}_{\dot{\alpha}} = - \partial_{\dot{\alpha}} - i \theta^{\alpha} \sigma^\mu_{\alpha\dot{\alpha}} \partial_{\mu}.
\] (9.12)

They satisfy the anticommutation relations:

\[
\{D_\alpha, \bar{D}_{\dot{\alpha}}\} = -2i \sigma^\mu_{\alpha \dot{\alpha}} \partial_{\mu}; \quad \{D_\alpha, D_\beta\} = \{\bar{D}_{\dot{\alpha}}, \bar{D}_{\dot{\beta}}\} = 0.
\] (9.13)

We can use the \( D \)s to construct irreducible representations of the supersymmetry algebra. Because the \( D \)s anticommute with the \( Q \)s, the condition

\[
\bar{D}_{\dot{\alpha}} \Phi = 0
\] (9.14)

is invariant under supersymmetry transformations. Fields that satisfy this condition are called chiral superfields. To construct chiral superfields, we would like to find combinations of \( x^\mu, \theta \) and \( \bar{\theta} \) which are annihilated by \( \bar{D}_{\dot{\alpha}} \). Writing

\[
y^\mu = x^\mu + i \theta \sigma^\mu \bar{\theta},
\] (9.15)
then
\[ \Phi = \Phi(y) = \phi(y) + \sqrt{2} \theta \psi(y) + \theta^2 F(y) \] (9.16)
is a chiral (scalar) superfield. Expanding in \( \theta \), the expansion terminates:
\[ \Phi = \phi(x) + i \theta \sigma^\mu \bar{\theta} \partial_\mu \phi + \frac{1}{4} \theta^2 \bar{\theta}^2 \partial^2 \phi \] (9.17)
\[ + \sqrt{2} \theta \psi - \frac{i}{\sqrt{2}} \theta \bar{\theta} \partial_\mu \psi \sigma^\mu \bar{\theta} + \theta^2 F. \]

We can work out the transformation laws. Starting with
\[ \delta \Phi = \epsilon^\alpha Q_\alpha \Phi + \epsilon_\alpha \bar{Q}^\alpha \] (9.18)
the components transform as
\[ \delta \phi = \sqrt{2} \epsilon \psi \delta \psi = \sqrt{2} \epsilon F + \sqrt{2} i \sigma^\mu \epsilon^* \partial_\mu \phi \] (9.19)
\[ \delta F = i \sqrt{2} \epsilon^* \bar{\sigma}^\mu \partial_\mu \psi. \]

Vector superfields form another irreducible representation of the algebra; they satisfy the condition
\[ V = V^\dagger. \] (9.20)

Again, it is easy to check that this condition is preserved by supersymmetry transformations. \( V \) can be expanded in a power series in \( \theta \)s:
\[ V = i \chi - i \chi^\dagger - \theta \sigma^\mu \theta^* A_\mu + i \theta^2 \bar{\theta} \bar{\chi} - i \bar{\theta}^2 \theta \lambda + \frac{1}{2} \theta^2 \bar{\theta}^2 D. \] (9.21)

Here \( \chi \) is not quite a chiral field; it is a superfield which is a function of \( \theta \) only, i.e. it has terms with zero, one or two \( \theta \)s; \( \chi^* \) is its conjugate.

If \( V \) is to describe a massless field, the presence of \( A_\mu \) indicates that there should be some underlying gauge symmetry, which generalizes the conventional transformation of bosonic theories. In the case of a \( U(1) \) theory, gauge transformations act by
\[ V \rightarrow V + i \Lambda - i \Lambda^\dagger \] (9.22)
where \( \Lambda \) is a chiral field. The \( \theta \theta^* \) term in \( \Lambda \) is precisely a conventional gauge transformation of \( A_\mu \). In the case of a \( U(1) \) theory, one can define a gauge-invariant field strength,
\[ W_\alpha = -\frac{1}{4} \bar{D}^2 D_\alpha V. \] (9.23)

By a gauge transformation, we can set \( \chi = 0 \). The resulting gauge is known as the Wess–Zumino gauge. This gauge is analogous to Coulomb gauge in
electrodynamics:

\[ W_\alpha = -i\lambda_\alpha + \theta_\alpha D - \sigma^{\mu\nu}_\alpha F_{\mu\nu}\theta_\beta + \theta^2 \sigma^\mu_{\alpha\beta} \partial_\mu \lambda^{\gamma\dot{\beta}}. \]  

(9.24)

The gauge transformation of a chiral field of charge \( q \) is:

\[ \Phi \rightarrow e^{-iq\Lambda} \Phi. \]  

(9.25)

One can form gauge-invariant combinations using the vector field (connection) \( V \):

\[ \Phi^\dagger e^{+qV} \Phi. \]  

(9.26)

We can also define a gauge-covariant derivative by

\[ D_\alpha \Phi = D_\alpha \Phi + D_\alpha V \Phi. \]  

(9.27)

This construction has a non-Abelian generalization. It is most easily motivated by generalizing first the transformation of \( \Phi \):

\[ \Phi \rightarrow e^{-i\Lambda} \Phi \]  

(9.28)

where \( \Lambda \) is now a matrix-valued chiral field.

Now we want to combine \( \phi^\dagger \) and \( \phi \) in a gauge-invariant way. By analogy to what we did in the Abelian case, we introduce a matrix-valued field, \( V \), and require that

\[ \Phi^\dagger e^V \Phi \]  

(9.29)

be gauge-invariant. So we require:

\[ e^V \rightarrow e^{-i\Lambda^*} e^{iV} e^{i\Lambda}. \]  

(9.30)

From this, we can define a gauge-covariant field strength,

\[ W_\alpha = -\frac{1}{4} D^2 e^{-V} D_\alpha e^V. \]  

(9.31)

This transforms under gauge transformations like a chiral field in the adjoint representation:

\[ W_\alpha \rightarrow e^{i\Lambda} W_\alpha e^{-i\Lambda}. \]  

(9.32)

### 9.3 \( N = 1 \) Lagrangians

In ordinary field theories, we construct Lagrangians invariant under translations by integrating densities over all of space. The Lagrangian changes by a derivative under translations, so the action is invariant. Similarly, if we start with a Lagrangian density in superspace, a supersymmetry transformation acts by differentiation with respect to \( x \) or \( \theta \). So integrating the variation over the full superspace
9.3 $N = 1$ Lagrangians

gives zero. This is the basic feature of the integration rules we introduced earlier. In equations:

$$
\delta \int d^4 x \int d^4 \theta h(\Phi, \Phi^\dagger, V) = \int d^4 x d^4 \theta (\epsilon^a Q_a + \epsilon_a Q^a)h(\Phi, \Phi^\dagger, V) = 0.
$$

(9.33)

For chiral fields, integrals over half of superspace are invariant. If $f(\Phi)$ is a function of chiral fields only, $f$ itself is chiral. As a result,

$$
\delta \int d^4 x d^2 \theta f(\Phi) = \int d^4 x d^2 \theta (\epsilon^a Q_a + \epsilon_a Q^a) f(\Phi).
$$

(9.34)

The integrals over the $Q_a$ terms vanish when integrated over $x$ and $d^2 \theta$. The $Q^*$ terms also give zero. To see this, note that $f(\Phi)$ is itself chiral (check), so

$$
\bar{Q}_a f \propto \theta^a \sigma^\mu \alpha \partial_\mu f.
$$

(9.35)

We can construct a general Lagrangian for a set of chiral fields, $\Phi_i$, and gauge group $G$. The chiral fields have dimension one (again, note that the $\theta$s have dimension $-1/2$). The vector fields, $V$, are dimensionless, while $W_\alpha$ has dimension $3/2$. With these ingredients, we can write down the most general renormalizable Lagrangian. First, there are terms involving integration over the full superspace:

$$
L_{\text{kin}} = \int d^4 \theta \sum_i \Phi_i^\dagger e^V \Phi_i,
$$

(9.36)

where the $e^V$ is in the representation of the gauge group appropriate to the field $\Phi_i$. We can also write an integral over half of superspace:

$$
L_W = \int d^2 \theta W(\Phi_i) + \text{c.c.}
$$

(9.37)

$W(\Phi)$ is a holomorphic function of the $\Phi_i$s (it is a function of $\Phi_i$, not $\Phi_i^\dagger$), called the superpotential. For a renormalizable theory,

$$
W = \frac{1}{2} m_{ij} \Phi_i \Phi_j + \frac{1}{3} \Gamma_{ijk} \Phi_i^\dagger \Phi_j \Phi_k.
$$

(9.38)

Finally, for the gauge fields, we can write:

$$
L_{\text{gauge}} = \frac{1}{g^{(i)2}} \int d^2 \theta W_\alpha^{(i)2}.
$$

(9.39)

The full Lagrangian density is

$$
\mathcal{L} = L_{\text{kin}} + L_W + L_{\text{gauge}}.
$$

(9.40)

The superspace formulation has provided us with a remarkably simple way to write the general Lagrangian. In this form, however, the meaning of these various
Supersymmetry terms is rather opaque. We would like to express them in terms of component fields. We can do this by using our expressions for the fields in terms of their components, and our simple integration table. Let’s first consider a single chiral field, $\Phi$, neutral under any gauge symmetries. Then

$$\mathcal{L}_{\text{kin}} = |\partial_\mu \Phi|^2 + i \psi_\Phi \sigma^\mu \psi^*_\Phi + F^*_\Phi F_\Phi.$$  \hfill (9.41)

The field $F$ is referred to as an “auxiliary field,” as it appears without derivatives in the action. Its equation of motion will be algebraic, and can be easily solved. It has no dynamics. For several fields, labeled with an index $i$, the generalization is immediate:

$$\mathcal{L}_{\text{kin}} = |\partial_\mu \phi_i|^2 + i \psi_i \sigma^\mu \psi^*_i + F^*_i F_i.$$  \hfill (9.42)

It is also easy to work out the component form of the superpotential terms. We will write this for several fields:

$$\mathcal{L}_W = \frac{\partial W}{\partial \Phi_i} F_i + \frac{\partial^2 W}{\partial \Phi_i \partial \Phi_j} \psi_i \psi_j.$$  \hfill (9.43)

For our special choice of superpotential this is:

$$\mathcal{L}_W = F_i (m_{ij} \Phi_j + \lambda_{ijk} \Phi_j \Phi_k) + (m_{ij} + \lambda_{ijk} \Phi_k) \psi_i \psi_j + \text{c.c.}$$  \hfill (9.44)

It is a simple matter to solve for the auxiliary fields:

$$F^*_i = -\frac{\partial W}{\partial \Phi_i}.$$  \hfill (9.45)

Substituting back in the Lagrangian,

$$V = |F_i|^2 = \left|\frac{\partial W}{\partial \Phi_i}\right|^2.$$  \hfill (9.46)

To work out the couplings of the gauge fields, it is convenient to choose the Wess–Zumino gauge. Again, this is analogous to the Coulomb gauge, in that it makes manifest the physical degrees of freedom (the gauge bosons and gauginos), but the supersymmetry is not explicit. We will leave performing the integrations over superspace to the exercises, and just quote the full Lagrangian in terms of the component fields:

$$\mathcal{L} = -\frac{1}{4} g_a^{-2} F_{\mu \nu}^a - i \lambda^a \sigma^\mu D_\mu \lambda^a + |D_\mu \phi_i|^2 - i \psi_i \sigma^\mu D_\mu \psi^*_i$$

$$+ \frac{1}{2 g^2} (D^a)^2 + D^a \sum_i \phi^*_i T^a \phi_i + F^*_i F_i - F_i \frac{\partial W}{\partial \phi_i} + \text{c.c.}$$

$$+ \sum_{ij} \frac{1}{2} \frac{\partial^2 W}{\partial \phi_i \partial \phi_j} \psi_i \psi_j + i \sqrt{2} \sum \lambda^a \psi_i T^a \phi^*_i.$$  \hfill (9.47)
The scalar potential is found by solving for the auxiliary $D$ and $F$ fields:

$$V = |F_i|^2 + \frac{1}{2g_a^2}(D^a)^2$$

with

$$F_i = \frac{\partial W}{\partial \phi^*_i}, \quad D^a = \sum_i (g^a \phi^*_i T^a \phi_i).$$

In the case there is a $U(1)$ factor in the gauge group, there is one more term one can include in the Lagrangian, known as the Fayet–Iliopoulos $D$ term. In superspace,

$$\xi \int d^4 \theta V$$

is supersymmetric and gauge invariant, since the integral $\int d^4 \Phi$ vanishes for any chiral field. In components, this is simply a term linear in $D, \xi D$, so, solving for $D$ from its equations of motion,

$$D = \xi + \sum_i q_i \phi^*_i \phi_i.$$
Integrating by parts, we have that $K^\mu - T^\mu$ is conserved. Taking this into account, for a theory with a single chiral field:

$$j_\alpha^\mu = \sqrt{2} \sigma_{\alpha\beta} \tilde{\sigma}^{\mu\gamma} \psi_{\gamma} \phi^* + i \sqrt{2} F^{\alpha\beta} \psi_{\beta}^*,$$

(9.54)

and similarly for $j_{\dot{\alpha}}^\mu$. The generalization for several chiral fields is obvious; one replaces $\psi \rightarrow \psi_i$, $\phi \rightarrow \phi_i$, etc., and sums over $i$. One can check that the (anti)commutator of the $Q$s (integrals over $j^0$) with the various fields gives the correct transformations laws. One can do the same for gauge fields. Working with the action written in terms of $W$, there are no derivatives, so the variation of the Lagrangian comes entirely from the $\partial_\mu K^\mu$ term in Eq. (9.53). We have already seen that the variation of $\int d^2\theta$ is a total derivative. The current is worked out in the exercises at the end of this chapter.

### 9.5 The ground-state energy in globally supersymmetric theories

One striking feature of the Lagrangian of Eq. (9.47) is that $V \geq 0$. This fact can be traced back to the supersymmetry algebra. Start with the equation

$$\{Q_\alpha, \tilde{Q}_{\dot{\beta}}\} = 2 P^\mu \sigma_{\alpha\dot{\beta}}^\mu,$$

(9.55)

multiply by $\sigma^0$ and take the trace:

$$Q_\alpha \tilde{Q}_{\dot{\alpha}} + \tilde{Q}_{\dot{\alpha}} Q_\alpha = E.$$  

(9.56)

Since the left-hand side is positive, the energy is always greater than or equal to zero.

In global supersymmetry, $E = 0$ is very special: the expectation value of the energy is an order parameter for supersymmetry breaking. If supersymmetry is unbroken, $Q_\alpha |0\rangle = 0$, so the ground-state energy vanishes if and only if supersymmetry is unbroken.

Alternatively, consider the supersymmetry transformation laws for $\lambda$ and $\psi$. One has, under a supersymmetry transformation with parameter $\epsilon$,

$$\delta \psi = \sqrt{2} \epsilon F + \cdots \quad \delta \lambda = i \epsilon D + \cdots.$$  

(9.57)

In the quantum theory, the supersymmetry transformation laws become operator equations

$$\delta \psi = i \{Q, \psi\},$$

(9.58)

so taking the vacuum expectation value of both sides, we see that a non-vanishing $F$ means broken supersymmetry; again vanishing of the energy, or not, is an indicator of supersymmetry breaking. So if either $F$ or $D$ has an expectation value, supersymmetry is broken.
9.6 Some simple models

The signal of ordinary (bosonic) symmetry breakdown is a Goldstone boson. In the case of supersymmetry, the signal is the presence of a Goldstone fermion, or goldstino. One can prove a goldstino theorem in almost the same way one proves Goldstone’s theorem. We will do this shortly, when we consider simple models of supersymmetry and its breaking.

9.6 Some simple models

In this section, we consider some simple models, to develop some practice with supersymmetric Lagrangians and to illustrate how supersymmetry is realized in the spectrum.

9.6.1 The Wess–Zumino model

One of the earliest, and simplest, models is the Wess–Zumino model, a theory of a single chiral field (no gauge interactions). For the superpotential, we take:

$$W = \frac{1}{2} m \phi^2 + \frac{\lambda}{3} \phi^3.$$  \hspace{1cm} (9.59)

The scalar potential is (using $\phi$ for the super and scalar field)

$$V = |m \phi + \lambda \phi^2|^2$$  \hspace{1cm} (9.60)

and the $\phi$ field has mass-squared $|m|^2$. The fermion mass term is

$$\frac{1}{2} m \psi \psi$$  \hspace{1cm} (9.61)

so the fermion also has mass $m$.

Let’s consider the symmetries of the model. First, set $m = 0$. The theory then has a continuous global symmetry. This is perhaps not obvious from the form of the superpotential, $W = (\lambda/3)\phi^3$. But the Lagrangian is an integral over superspace of $W$, so it is possible for $W$ to transform and for the $\theta$s to transform in a compensating fashion. Such a symmetry, which does not commute with supersymmetry, is called an R symmetry. If, by convention, we take the $\theta$s to carry charge 1, than the $d\theta$s carry charge $-1$ (think of the integration rules). So the superpotential must carry charge 2. In the present case, this means that $\phi$ carries charge $2/3$. Note that each component of the superfield transforms differently:

$$\phi \to e^{i\frac{2}{3}\alpha} \phi \quad \psi \to e^{i\left(\frac{2}{3} - 1\right)\alpha} \psi \quad F \to e^{i\left(\frac{2}{3} - 2\right)\alpha} F.$$  \hspace{1cm} (9.62)

Now consider the problem of mass renormalization at one loop in this theory. First suppose that $m = 0$. From our experience with non-supersymmetric theories, we might expect a quadratically divergent correction to the scalar mass. But $\phi^2$
carries charge 4/3, and this forbids a mass term in the superpotential. For the fermion, the symmetry does not permit one to draw any diagram which corrects the mass. But for the boson, there are two diagrams, one with intermediate scalars, one with fermions. We will study these in detail later. Consistent with our argument, however, these two diagrams cancel.

What if, at tree level, \( m \neq 0 \)? We will see shortly that there are still no corrections to the mass term in the superpotential. In fact, perturbatively, there are no corrections to the superpotential at all. There are, however, wave-function renormalizations; rescaling \( \phi \) corrects the masses. In four dimensions, the wave-function corrections are logarithmically divergent, so there are logarithmically divergent corrections to the masses, but there are no quadratic divergences.

### 9.6.2 A U(1) gauge theory

Consider a \( U(1) \) gauge theory, with two charged chiral fields, \( \phi^+ \) and \( \phi^- \), with charges \( \pm 1 \), respectively. First suppose that the superpotential vanishes. Our experience with ordinary field theories would suggest that we start developing a perturbation expansion about the point in field space \( \phi^\pm = 0 \). But consider the potential in this theory. In Wess–Zumino gauge:

\[
V(\phi^\pm) = \frac{1}{2} D^2 = \frac{g^2}{2}(|\phi^+|^2 - |\phi^-|^2)^2.
\]

(9.63)

Zero energy, supersymmetric minima have \( D = 0 \). By a gauge choice, we can set

\[
\phi^+ = v \quad \phi^- = v' e^{i\alpha}.
\]

(9.64)

Then \( D = 0 \) if \( v = v' \). In field theory, as discussed in Section 2.3, when one has such a continuous degeneracy, just as in the case of global symmetry breaking, one must choose a vacuum. Each vacuum is physically distinct – in this case, the spectra are different – and there are no transitions between vacua.

It is instructive to work out the spectrum in a vacuum with a given \( v \). One has, first, the gauge bosons, with masses:

\[
m^2_v = 4g^2v^2.
\]

(9.65)

This accounts for three degrees of freedom. From the Yukawa couplings of the gaugino, \( \lambda \), to the \( \phi \)s, one has a term:

\[
\mathcal{L}_\lambda = \sqrt{2} g v \lambda (\psi\phi^+ - \psi\phi^-),
\]

(9.66)

so we have a Dirac fermion with mass \( 2gv \). So we now have accounted for three bosonic and two fermionic degrees of freedom. The fourth bosonic degree of freedom is a scalar; one can think of it as the “partner” of the Higgs which is eaten in
the Higgs phenomenon. To compute its mass, note that, expanding the scalars as

$$\phi^\pm = v + \delta\phi^\pm$$  \hspace{1cm} (9.67)

$$D = g v (\delta\phi^+ + \delta\phi^+ - \delta\phi^- - \delta\phi^-).$$  \hspace{1cm} (9.68)

So $D^2$ gives a mass to the real part of $\delta\phi^+ - \delta\phi^-$, equal to the mass of the gauge bosons and gauginos. Since the masses differ in states with different $v$, these states are physically inequivalent.

There is also a massless state: a single chiral field. For the scalars, this follows on physical grounds: the expectation value, $v$, is undetermined and one phase is undetermined, so there is a massless complex scalar. For the fermions, the linear combination $\psi_{\phi^+} + \psi_{\phi^-}$ is massless. So we have the correct number of fields to construct a massless chiral multiplet. We can describe this elegantly by introducing the composite chiral superfield:

$$\Phi = \phi^+\phi^- \approx v^2 + v (\delta\phi^+ + \delta\phi^-).$$  \hspace{1cm} (9.69)

Its components are precisely the massless complex scalar and chiral fermion which we identified above.

This is our first encounter with a phenomenon which is nearly ubiquitous in supersymmetric field theories and string theory. There are often continuous sets of vacuum states, at least in some approximation. The set of such physically distinct vacua is known as the “moduli space.” In this example, the set of such states is parameterized by the values of the field, $\Phi$; $\Phi$ is called a “modulus.”

In quantum mechanics, in such a situation, we would solve for the wave function of the modulus, and the ground state would typically involve a superposition of the different classical ground states. We have seen, though, that, in field theory, one must choose a value of the modulus field. In the presence of such a degeneracy, for each such value one has, in effect, a different theory – no physical process leads to transitions between one such state and another. Once the degeneracy is lifted, however, this is no longer the case, and transitions, as we will frequently see, are possible.

### 9.7 Non-renormalization theorems

In ordinary field theories, as we integrate out physics between one scale and another, we generate every term in the effective action permitted by symmetries. This is not the case in supersymmetric field theories. This feature gives such theories surprising, and possibly important, properties when we consider questions of naturalness. It also gives us a powerful tool to explore the dynamics of these theories, even at strong coupling. This power comes easily; in this section, we will enumerate these theorems and explain how they arise.
So far, we have restricted our attention to renormalizable field theories. But we have seen that, in considering physics beyond the Standard Model, we may wish to relax this restriction. It is not hard to write down the most general, globally supersymmetric theory with at most two derivatives, using the superspace formalism:

\[ \mathcal{L} = \int d^4 \theta K(\phi, \phi^\dagger) + \int d^2 \theta W(\phi) + \text{c.c.} + \int d^2 \theta f_a(\phi)(W_a^{(a)})^2 + \text{c.c.} \]  

(9.70)

The function \( K \) is known as the Kahler potential. Its derivatives dictate the form of the kinetic terms for the different fields. The functions \( W \) and \( f_a \) are holomorphic (what physicists would comfortably call “analytic”) functions of the chiral fields. In terms of component fields (see the exercises) the real part of \( f \) couples to \( F_{\mu\nu}^2 \); these functions thus determine the gauge couplings. The imaginary parts couple to the now-familiar operator \( F\tilde{F} \). These features of the Lagrangian will be important in much of our discussion of supersymmetric field theories and string theory.

Non-supersymmetric theories have the property that they tend to be generic; any term permitted by symmetries in the theory will appear in the effective action, with an order of magnitude determined by dimensional analysis.\(^1\) Supersymmetric theories are special in that this is not the case. In \( N = 1 \) theories, there are non-renormalization theorems governing the superpotential and the gauge coupling functions, \( f \), of Eq. (9.70). These theorems assert that the superpotential is not corrected in perturbation theory beyond its tree level value, while \( f \) is at most renormalized at one loop.\(^2\)

Originally, these theorems were proven by detailed study of Feynman diagrams. Seiberg has pointed out that they can be understood in a much simpler way. Both the superpotential and the functions \( f \) are holomorphic functions of the chiral fields, i.e. they are functions of the \( \phi_i \)s and not the \( \phi_i^\dagger \)s. This is evident from their construction. Seiberg argued that the coupling constants of a theory may be thought of as expectation values of chiral fields and so the superpotential must be a holomorphic function of these as well. For example, consider a theory of a single chiral field, \( \Phi \), with superpotential

\[ W = (m \Phi^2 + \lambda \Phi^3). \]  

(9.71)

We can think of \( \lambda \) and \( m \) as expectation values of chiral fields, \( \lambda(x, \theta) \) and \( m(x, \theta) \).

In the Wess–Zumino Lagrangian, if we first set \( \lambda \) to zero, there is an \( R \) symmetry under which \( \Phi \) has \( R \) charge 1 and \( \lambda \) has \( R \) charge \(-1\). Now consider corrections to the effective action in perturbation theory. For example, renormalizations of \( \lambda \) in

---

\(^1\) In some cases, there may be suppression by a few powers of coupling.

\(^2\) There is an important subtlety connected with these theorems. Both should be interpreted as applying only to a “Wilsonian” effective action, in which one integrates out physics above some scale, \( \mu \). If infrared physics is included, the theorems do not necessarily hold. This is particularly important for the gauge couplings.
the superpotential necessarily involve positive powers of $\lambda$. But such terms (apart from $(\lambda)^{1/1}$) have the wrong $R$ charge to preserve the symmetry. So there can be no renormalization of this coupling. There can be wave-function renormalization, since $K$ is not holomorphic, so $K = K(\lambda^\dagger \lambda)$ is allowed, in general.

There are many interesting generalizations of these ideas, and I won’t survey them here, but I will mention two further examples. First, gauge couplings can be thought of in the same way, i.e. we can treat $g^{-2}$ as part of a chiral field. More precisely, we define:

$$S = \frac{8\pi^2}{g^2} + ia + \cdots. \quad (9.72)$$

The real part of the scalar field in this multiplet couples to $F_{\mu\nu}^2$, but the imaginary part, $a$, couples to $F \tilde{F}$. Because $F \tilde{F}$ is a total derivative, in perturbation theory there is a symmetry under constant shifts of $a$. The effective action should respect this symmetry. Because the gauge coupling function, $f$, is holomorphic, this implies that

$$f(g^2) = S + \text{const} = \frac{8\pi^2}{g^2} + \text{const}. \quad (9.73)$$

The first term is just the tree level term. One-loop corrections yield a constant, but there are no higher order corrections in perturbation theory! This is quite a striking result. It is also paradoxical, since the two-loop beta functions for supersymmetric Yang–Mills theories have been computed long ago, and are, in general, non-zero. The resolution of this paradox is subtle and interesting. It provides a simple computation of the two-loop beta function. In a particular renormalization scheme, it gives an exact expression for the beta function. This is explained in Appendix D.

Before explaining the resolution of this paradox, there is one more non-renormalization theorem which we can prove rather trivially here. This is the statement that if there is no Fayet–Iliopoulos $D$ term at tree level, this term can be generated at most at one loop. To prove this, write the $D$ term as

$$\int d^4\theta d(g, \lambda)V. \quad (9.74)$$

Here $d(g, \lambda)$ is some unknown function of the gauge and other couplings in the theory. But if we think of $g$ and $\lambda$ as chiral fields, this expression is only gauge invariant if $d$ is a constant, corresponding to a possible one-loop contribution. Such contributions do arise in string theory.

In string theory, all of the parameters are expectation values of chiral fields. Indeed, non-renormalization theorems in string theory, both for world sheet and string perturbation theory, were proved by the sort of reasoning we have used above.
9.8 Local supersymmetry: supergravity

If supersymmetry has anything to do with nature, and if it is not merely an accident, then it must be a local symmetry. There is not space here for a detailed exposition of local supersymmetry. For most purposes, both theoretical and phenomenological, there are, fortunately, only a few facts we will need to know. The field content (in four dimensions) is like that of global supersymmetry, except that now one has a graviton and a gravitino. Note that the number of additional bosonic and fermionic degrees of freedom (a minimal requirement if the theory is to be supersymmetric) is the same. The graviton is a traceless, symmetric tensor; in \( d − 2 \) dimensions, this has two independent components. Similarly, the gravitino, \( \psi_\mu \), has both a vector and a spinor index. It satisfies a constraint similar to tracelessness:

\[
\gamma^\mu \psi_\mu = 0. \tag{9.75}
\]

In \( d − 2 \) dimensions, this is two conditions, leaving two physical degrees of freedom.

As in global supersymmetry (without the restriction of renormalizability), the terms in the effective action with at most two derivatives or four fermions are completely specified by three functions.

1. The Kahler potential, \( K(\phi, \phi^\dagger) \), a function of the chiral fields.
2. The superpotential, \( W(\phi) \), a holomorphic function of the chiral fields.
3. The gauge coupling functions, \( f_a(\phi) \), which are also holomorphic functions of the chiral fields.

The Lagrangian which follows from these is quite complicated, including many two- and four-fermion interactions. It can be found in the suggested reading. Our main concern in this text will be the scalar potential. This is given by

\[
V = e^K \left[ \left( \frac{\partial W}{\partial \phi_i} + \frac{\partial K}{\partial \phi_i} \right) g^{ij} \left( \frac{\partial W^*_j}{\partial \phi^*_j} + \frac{\partial K}{\partial \phi^*_j} \right) - 3|W|^2 \right], \tag{9.76}
\]

where

\[
g_{i\bar{j}} = \frac{\partial^2 K}{\partial \phi_i \partial \phi^*_j} \tag{9.77}
\]

is the (Kahler) metric associated with the Kahler potential. In this equation, we have adopted units in which \( M = 1 \), where

\[
G_N = \frac{1}{8\pi M^2}. \tag{9.78}
\]

\( M \approx 2 \times 10^{18} \text{ GeV} \) is known as the reduced Planck mass.
Exercises

Suggested reading

The text by Wess and Bagger (1992) provides a good introduction to superspace, the fields and Lagrangians of supersymmetric theories in four dimensions, and supergravity. Other texts include those by Gates et al. (1983) and Mohapatra (2003). Appendix B of Polchinski’s (1998) text provides a concise introduction to supersymmetry in higher dimensions. The supergravity Lagrangian is derived and presented in its entirety in Cremmer et al. (1979) and Wess and Bagger (1992) and is reviewed, for example, in Nilles (1984). Non-renormalization theorems were first discussed from the viewpoint presented here by Seiberg (1993).

Exercises

(1) Verify the commutators of the $Q$s and the $D$s.
(2) Check that with the definition, Eq. (9.15), $\Phi$ is chiral. Show that any function of chiral fields is a chiral field.
(3) Verify that $W_\alpha$ transforms as in Eq. (9.32), and that $\text{Tr}W_\alpha^2$ is gauge invariant.
(4) Derive the expression (9.47) for the component Lagrangian including gauge interactions and the superpotential by doing the superspace integrals. For an $SU(2)$ theory with a scalar triplet, $\vec{\phi}$, and singlet, $X$, take $W = \lambda(\vec{\phi}^2 - \mu^2)$. Find the ground state and work out the spectrum.
(5) Derive the supersymmetry current for a theory with several chiral fields. For a single field, $\Phi$, and $W = 1/2 m \Phi^2$, verify, using the canonical commutation relations, that the $Q$s obey the supersymmetry algebra. Work out the supercurrent for a pure supersymmetric gauge theory.
A first look at supersymmetry breaking

If supersymmetry has anything to do with the real world, it must be a broken symmetry. In the globally supersymmetric framework we have presented so far, this breaking could be spontaneous or explicit. Once we promote the symmetry to a local symmetry, as we will argue later, the breaking of supersymmetry must be spontaneous. However, as we will also see, at low energies, the theory can appear to be a globally supersymmetric theory with explicit, “soft,” breaking of the symmetry. In this chapter, we will discuss some of the features of both spontaneous and explicit breaking.

10.1 Spontaneous supersymmetry breaking

We have seen that supersymmetry breaking is signalled by a non-zero expectation value of an $F$ component of a chiral or $D$ component of a vector superfield. Models involving only chiral fields with no supersymmetric ground state are referred to as O’Raifeartaigh models. A simple example has three singlet fields, $A$, $B$, and $X$, with superpotential:

$$W = \lambda A(X^2 - \mu^2) + mBX.$$  \hfill (10.1)

With this superpotential, the equations

$$F_A = \frac{\partial W}{\partial A} = 0 \quad F_B = \frac{\partial W}{\partial B} = 0$$  \hfill (10.2)

are incompatible. To actually determine the expectation values and the vacuum energy, it is necessary to minimize the potential. There is no problem satisfying the equation $F_X = 0$. So we need to minimize

$$V_{\text{eff}} = |F_A|^2 + |F_B|^2 = |\lambda|^2 |X^2 - \mu^2|^2 + m^2 |X|^2.$$  \hfill (10.3)
10 A first look at supersymmetry breaking

Assuming $\mu^2$ and $\lambda$ are real, the solutions are:

$$X = 0 \quad X^2 = \frac{2\lambda^2 \mu^2 - m^2}{2\lambda^2}.$$  \(10.4\)

The corresponding vacuum energies are:

$$V_0^{(a)} = |\lambda^2 \mu^4|; \quad V_0^{(b)} = m^2 \mu^2 - \frac{m^4}{4\lambda^2}.$$  \(10.5\)

The vacuum at $X \neq 0$ disappears at a critical value of $\mu$.

Let’s consider the spectrum in the first of these (with $X = 0$). We focus, in particular, on the massless states. First, there is a massless scalar. This arises because, at this level, not all of the fields are fully determined. The equation

$$\frac{\partial W}{\partial X} = 0$$  \(10.6\)

can be satisfied provided

$$2\lambda A X + m B = 0.$$  \(10.7\)

This vacuum degeneracy is accidental, and as we will later see, is lifted by quantum corrections.

There is also a massless fermion, $\psi_A$. This fermion is the goldstino. Replacing the auxiliary fields in the supersymmetry current for this model (Eq. (9.54)) gives

$$j_\mu^\alpha = i \sqrt{2} F_A \sigma^\mu_{\alpha \dot{\alpha}} \psi_A^* \dot{\psi}_{\dot{\alpha}}.$$  \(10.8\)

You should check that the massive states do not form Bose–Fermi degenerate multiplets.

10.1.1 The Fayet–Iliopoulos D term

It is also possible to generate an expectation value for a $D$ term. In the case of a $U(1)$ gauge symmetry, we saw that

$$\mu^2 \int d^4 \theta \ V = \mu^2 D$$  \(10.9\)

is gauge invariant. Under the transformation $\delta V = \Lambda + \Lambda^\dagger$, the integrals over the chiral and anti-chiral fields, $\Lambda$ and $\Lambda^\dagger$, are zero. This can be seen either by doing the integration directly, or by noting that differentiation by Grassmann numbers is equivalent to integration (recall our integral table). As a result, for example, $\int d^2 \theta \propto (\bar{D})^2$. This Fayet–Iliopoulos $D$ term can lead to supersymmetry breaking. For example, if one has two charged fields, $\Phi^\pm$, with charges $\pm 1$, and superpotential $m \Phi^+ \Phi^-$, one cannot simultaneously make the two auxiliary $F$ fields and the auxiliary $D$ field vanish.
One important feature of both types of models is that at tree level, in the context of global supersymmetry, the spectra are never realistic. These spectra satisfy a sum rule,

$$\sum (-1)^F m^2 = 0.$$  \hspace{1cm} (10.10)

Here \((-1)^F = 1\) for bosons and \(-1\) for fermions. This guarantees that there are always light states, and often color and/or electromagnetism are broken. These statements are not true of radiative corrections, and of supergravity, as we will explain later.

It is instructive to prove this sum rule. Consider a theory of chiral fields only (no gauge interactions). The potential is given by

$$V = \sum_i \left| \frac{\partial W}{\partial \phi_i} \right|^2.$$  \hspace{1cm} (10.11)

The boson mass matrix has terms of the form \(\phi_i \phi_j^* + \text{c.c.}\), where we are using indices \(\bar{i}\) and \(\bar{j}\) for complex conjugate fields. The latter terms, as we will now see, are connected with supersymmetry breaking. The various terms in the mass matrix can be obtained by differentiating the potential:

$$m_{\bar{i}j}^2 = \frac{\partial^2 V}{\partial \phi_{\bar{i}} \partial \phi_j} = \frac{\partial^2 W}{\partial \phi_{\bar{i}} \partial \phi_k} \frac{\partial^2 W^*}{\partial \phi_k \partial \phi_j^*},$$  \hspace{1cm} (10.12)

$$m_{ij}^2 = \frac{\partial^2 V}{\partial \phi_i \partial \phi_j} = \frac{\partial W}{\partial \phi_k^*} \frac{\partial^3 W}{\partial \phi_k \partial \phi_i \partial \phi_j}. \hspace{1cm} (10.13)$$

The first of these terms has just the structure of the square of the fermion mass matrix,

$$\mathcal{M}_{\bar{i}j} = \frac{\partial^2 W}{\partial \phi_{\bar{i}} \partial \phi_j}. \hspace{1cm} (10.14)$$

So writing the boson mass, \(M_B^2\) matrix on the basis \((\phi_i \phi_j^*)\), we see that Eq. (10.10) holds.

The theorem is true whenever a theory can be described by a renormalizable effective action. Various non-renormalizable terms in the effective action can give additional contributions to the mass. For example, in our O’Raifeartaigh model, \(\int d^4\theta A^\dagger AZ^\dagger Z\) will violate the tree-level sum rule. Such terms arise in renormalizable theories when one integrates out heavy fields to obtain an effective action at some scale. In the context of supergravity, such terms are present already at tree level. This is perhaps not surprising, given that these theories are non-renormalizable and must be viewed as effective theories from the very beginning (perhaps the effective low-energy description of string theory). Shortly, we will
discuss the construction of realistic models. First, however, we turn to the issue of non-renormalization theorems and dynamical supersymmetry breaking.

### 10.2 The goldstino theorem

In each of the examples of supersymmetry breaking, there is a massless fermion in the spectrum. We might expect this, by analogy to Goldstone’s theorem. The essence of the usual Goldstone theorem is the statement that, for a spontaneously broken global symmetry, there is a massless scalar. There is a coupling of this scalar to the symmetry current. From Lorentz invariance (see Appendix B):

$$\langle 0 | j^\mu | \pi(p) \rangle = fp^\mu .$$

(10.15)

Correspondingly, in the low-energy effective field theory (valid below the scale of symmetry breaking) the current takes the form:

$$j^\mu = f \partial^\mu \pi(x) .$$

(10.16)

The analogous statements for spontaneous breaking of global supersymmetry are easy to prove. Suppose that the symmetry is broken by the $F$ component of a chiral field (this can be a composite field). Then we can study

$$\int d^4 x \partial_\mu e^{iq \cdot x} T\{ j^\mu_\alpha (x) \psi_\alpha (0) \} = 0 .$$

(10.17)

Here $j^\mu_\alpha$ is the supersymmetry current; its integral over space is the supersymmetry charge. This expression vanishes because it is an integral of a total derivative. Now taking the derivatives, there are two non-vanishing contributions: one from the derivative acting on the exponential; one from the action on the time-ordering symbol. Taking these derivatives, and then taking the limit $q \to 0$, gives

$$\langle \{ Q, \Psi_\Phi (0) \} \rangle = iq^\mu T\{ j^\mu_\alpha (x) \psi_\alpha (0) \} \bigg|_{E.T.} .$$

(10.18)

The left-hand side is constant, so the Green function on the right-hand side must be singular as $q \to 0$. By the usual spectral representation analysis, this shows that there is a massless fermion coupled to the supersymmetry current. In weakly coupled theories, we can understand this more simply. Recalling the form of the supersymmetry current, if one of the $F$s has an expectation value,

$$j^\mu_\alpha = i \sqrt{2} (\sigma^\mu)_{\alpha \dot{\alpha}} \psi^{\dot{\alpha}} F .$$

(10.19)

To leading order in fields, current conservation is just the massless Dirac equation. $F$, here, is the “goldstino decay constant.” We can understand the massless fermion which appeared in the O’Raifeartaigh model in terms of this theorem. It is easy to check that:

$$\psi_G \propto F_A \psi_A + F_B \psi_B .$$

(10.20)
10.3 Loop corrections and the vacuum degeneracy

We saw that in the O’Raifeartaigh model, at the classical level, there is a large vacuum degeneracy. To understand the model fully, we need to investigate the fate of this degeneracy in the quantum theory. Consider the vacuum with \( X = 0 \). In this case, \( A \) is undetermined at the classical level. But \( A \) is only an approximate modulus. At one loop, quantum corrections generate a potential for \( A \). Our goal is to integrate out the various massive fields to obtain the effective action for \( A \). At one loop, this is particularly easy. The tree-level mass spectrum depends on \( A \). The one-loop vacuum energy is:

\[
\sum_i (-1)^F \int \frac{d^3k}{(2\pi)^3} \frac{1}{2} \sqrt{k^2 + m_i^2}.
\] (10.21)

Here the sum is over all possible helicity states; again the factor \((-1)^F\) weights bosons with 1 and fermions with \(-1\). This expression, in field theory, is usually very divergent in the ultraviolet, but in the supersymmetric case, it is far less so. If supersymmetry is unbroken, the boson and fermion contributions cancel, and the correction simply vanishes. If supersymmetry is broken, the divergence is only logarithmic. To see this, we can simply study the integrand at large \( k \), expanding the square root in powers of \( m^2/k^2 \). The leading, quartically divergent term, is independent of \( m^2 \), and so vanishes. The next term is quadratically divergent, but it vanishes because of the sum rule: \( \sum (-1)^F m_i^2 = 0 \).

So at one loop the potential behaves as:

\[
V(A) = -\sum (-1)^F m_i^4 \int \frac{d^3k}{16(2\pi)^3 k^3} \approx \sum (-1)^F m_i^4 \frac{1}{64\pi^2} \ln \left( \frac{m_i^2}{\Lambda^2} \right).
\] (10.22)

To compute the potential precisely, we need to work out the spectrum as a function of \( A \). We will content ourselves with the limit of large \( A \). Then the spectrum consists of a massive fermion, \( \psi_X \), with mass \( 2\lambda A \), and the real and imaginary parts of the scalar components of \( X \), with masses:

\[
m^2_s = 4|\lambda^2 A^2| \pm 2\mu^2 \lambda^2 x^2.
\] (10.23)

So

\[
V(A) = |\lambda^2| \mu^4 \left( 1 + \frac{\lambda^2}{8\pi^2} \ln(|\lambda A|^2/\Lambda^2) \right).
\] (10.24)

This result has a simple interpretation. The leading term is the classical energy; the correction corresponds to replacing \( \lambda^2 \) by \( \lambda^2(A) \), the running coupling at scale \( A \). In this theory, a more careful study shows that the minimum of the potential is precisely at \( A = 0 \).
10 A first look at supersymmetry breaking

10.4 Explicit, soft supersymmetry breaking

Ultimately, if nature is supersymmetric, it is likely that we will want to understand supersymmetry breaking through some dynamical mechanism. But we can be more pragmatic, accept that supersymmetry is broken, and parameterize the breaking through mass differences between ordinary fields and their superpartners. It turns out that this procedure does not spoil the good ultraviolet properties of the theory. Such mass terms are said to be “soft” for precisely this reason.

We will consider soft breakings in more detail in the next chapter when we discuss the MSSM, but we can illustrate the main point simply. Take as a model the Wess–Zumino model, with $m = 0$ in the superpotential. Add to the Lagrangian an explicit mass term $m_{\text{soft}}^2 |\phi|^2$. Then we can calculate the one-loop correction to the scalar mass from the two graphs of Fig. 10.1. In the supersymmetric case, these two graphs cancel. With the soft breaking term, there is not an exact cancellation; instead one obtains:

$$
\delta m^2 = -\frac{|\lambda|^2}{16\pi^2} m_{\text{soft}}^2 \ln \left( \frac{\Lambda^2}{m_{\text{soft}}^2} \right). \quad (10.25)
$$

We can understand this simply on dimensional grounds. We know that, for $m_{\text{soft}}^2 = 0$, there is no correction. Treating the soft term as a perturbation, the result is necessarily proportional to $m_{\text{soft}}^2$; at most, then, any divergence must be logarithmic.

In addition to soft masses for scalars, one can also add soft masses for gauginos; one can also include trilinear scalar couplings. We can understand how these might arise at a more fundamental level, which also makes clear the sense in which these terms are soft. Suppose that we have a field, $Z$, with non-zero $F$ component, as in the O’Raifeartaigh model (but more generally). Suppose at tree level, there are no renormalizable couplings between $Z$ and the other fields of the model, which we will denote generically as $\phi$. Non-renormalizable couplings, such as

$$
\mathcal{L}_Z = \frac{1}{M^2} \int d^4\theta Z \phi^\dagger \phi,
$$

(10.26)
can be expected to arise in the effective Lagrangian; they are not forbidden by any symmetry. Replacing $Z$ by its expectation value, $\langle Z \rangle = \cdots + \theta^2 \langle F_Z \rangle$, gives a mass
10.5 Supersymmetry breaking in supergravity models

10.5.1 The Kähler Potential

The Kähler potential $K$ is a function of the scalar fields $\phi_i$, and plays a central role in the supergravity Lagrangian. It is defined by

$$ K = \ln \left( \frac{e^{i\phi_i}}{\sqrt{\prod \phi_i}} \right) $$

This potential ensures that the superpotential $W$ is holomorphic, i.e., it satisfies the condition $\partial_i W = 0$. The Kähler potential together with the superpotential $W$ and its derivatives provide the necessary ingredients to construct the supergravity Lagrangian.

10.5.2 The Superpotential

The superpotential $W$ is a function of the scalar fields $\phi_i$ and is a holomorphic function of these fields. It encodes the interactions of the scalars and plays a crucial role in the construction of the supergravity Lagrangian. The superpotential is given by

$$ W = W(\phi) $$

where $W(\phi)$ is a complex-valued function of the scalar fields $\phi_i$. The superpotential is a holomorphic function of the scalar fields, which ensures that the Kähler potential is well-defined and that the supergravity Lagrangian is consistent.
When this is not the case, supersymmetry is broken. If we require vanishing of the cosmological constant, then we have:

\[ 3|W|^2 = \sum_{i,j} D_i W D_j W^* g^{ij}. \] (10.32)

In this case, the gravitino mass turns out to be:

\[ m_{3/2} = \langle e^{-K/2} W \rangle. \] (10.33)

There is a standard strategy for building supergravity models. One introduces two sets of fields, the “hidden sector fields,” which will be denoted by \( Z_i \), and the “visible sector fields,” denoted by \( y_a \). The \( Z_i \)s are assumed to be connected with supersymmetry breaking, and to have only very small couplings to the ordinary fields, \( y_a \). In other words, one assumes that the superpotential, \( W \), has the form

\[ W = W(Z) + W_y(y), \] (10.34)

at least up to terms suppressed by \( 1/M \). The \( y \) fields should be thought of as the ordinary matter fields and their superpartners.

One also usually assumes that the Kahler potential has a “minimal” form,

\[ K = \sum Z_i^\dagger Z_i + \sum y_a^\dagger y_a. \] (10.35)

One chooses (tunes) the parameters of \( W_Z \) so that

\[ \langle F_Z \rangle \approx M_W M \] (10.36)

and

\[ \langle V \rangle = 0. \] (10.37)

Note that this means that

\[ \langle W \rangle \approx M_W M^2. \] (10.38)

The simplest model of the hidden sector is known as the “Polonyi model.” In this model,

\[ W = m^2(Z + \beta) \] (10.39)

\[ \beta = (2 + \sqrt{3})M. \] (10.40)

In global supersymmetry, with only renormalizable terms, this would be a rather trivial superpotential, but not so in supergravity. The minimum of the potential for \( Z \) lies at

\[ Z = (\sqrt{3} - 1)M \] (10.41)
and

\[ m_{3/2} = \left(\frac{m^2}{M}\right)e^{\left(\sqrt{3}-1\right)/2}. \] (10.42)

This symmetry breaking also leads to soft breaking mass terms for the fields \( y \).

There are terms of the form

\[ m_0^2|y_i|^2. \] (10.43)

These arise from the \(|\partial_i K \, W|^2 = |y_i|^2|W|^2\) terms in the potential. For the simple Kahler potential:

\[ m_0^2 = 2\sqrt{3}m_{3/2}^2 \quad A = (3 - \sqrt{3})m_{3/2}. \] (10.44)

If we now allow for a non-trivial \( W_y \), we also find supersymmetry-violating quadratic and cubic terms in the potential. These are known as the \( B \) and \( A \) terms, and have the form:

\[ B_{ij}m_{3/2}\phi_i\phi_j + A_{ijk}m_{3/2}\phi_i\phi_j\phi_k. \] (10.45)

For example, if \( W \) is homogeneous, and of degree three, there are terms in the supergravity potential of the form:

\[ e^K \frac{\partial W}{\partial y_a} \frac{\partial K}{\partial y^*_a} \langle W \rangle + \text{c.c.} = 3m_{3/2}W(y). \] (10.46)

Additional contributions arise from

\[ e^K \left( \frac{\partial W}{\partial z_i^*} \right) \langle z_i^* \rangle W^* + \text{c.c.} \] (10.47)

There are analogous contributions to the \( B \) terms. In the exercises, these are worked out for specific models.

Gaugino masses (both in local and global supersymmetry) can arise from a non-trivial gauge coupling function,

\[ f^a = \frac{cZ}{M}, \] (10.48)

which gives

\[ m_\lambda = \frac{cF_z}{M}. \] (10.49)

These models have just the correct structure to build a theory of TeV-scale supersymmetry, provided \( m_{3/2} \sim \text{TeV} \). They have soft breakings of the correct order of magnitude. We will discuss their phenomenology further when we discuss the Minimal Supersymmetric Standard Model in the next chapter.
Even without a deep understanding of local supersymmetry, there are a number of interesting observations we can make. Most important, our arguments for the renormalization of the superpotential in global supersymmetry remain valid here. This will be particularly important when we come to string theory, which is a locally supersymmetric theory.

**Suggested reading**

It was Witten (1981) who most clearly laid out the issues of supersymmetry breaking. This paper remains extremely useful and readable today. The notion that one should consider adding soft breaking parameters to the MSSM was developed by Dimopoulos and Georgi (1981). Good introductions to models with supersymmetry breaking in supergravity are provided by a number of review articles and textbooks, for example those of Mohapatra (2003) and Nilles (1984).

**Exercises**

1. Work out the spectrum of the O’Raifeartaigh model. Show that the spectrum is not supersymmetric, but verify the sum rule, $\sum (-1)^F \cdot m^2 = 0$.
2. Work out the spectrum of a model with a Fayet–Iliopoulos D term and supersymmetry breaking. Again verify the sum rule.
3. Check Eqs. (10.40)–(10.44) for the Polonyi model.
The Minimal Supersymmetric Standard Model

We can now very easily construct a supersymmetric version of the Standard Model. For each of the gauge fields of the usual Standard Model, we introduce a vector superfield. For each of the fermions (quarks and leptons) we introduce a chiral superfield with the same gauge quantum numbers. Finally, we need at least two Higgs doublet chiral fields; if we introduce only one, as in the simplest version of the Standard Model, the resulting theory possesses gauge anomalies and is inconsistent. So the theory is specified by the gauge group \((SU(3) \times SU(2) \times U(1))\) and enumerating the chiral fields:

\[
Q_f, \bar{u}_f, \bar{d}_f, L_f, \bar{e}_f \quad f = 1, 2, 3 \quad H_U, H_D.
\]  

(11.1)

The gauge invariant kinetic terms, auxiliary \(D\) terms, and gaugino–matter Yukawa couplings are completely specified by the gauge symmetries. The superpotential can be taken to be

\[
W = H_U(\Gamma_U)_{f,f'} Q_f \bar{U}_{f'} + H_D(\Gamma_D)_{f,f'} Q_f \bar{D}_{f'} + H_D(\Gamma_E)_{f,f'} L_f \bar{e}_{f'}.
\]  

(11.2)

If the Higgs obtain suitable expectation values, \(SU(2) \times U(1)\) is broken, and quarks and leptons acquire mass, just as in the Standard Model.

There are other terms which can also be present in the superpotential. These include the “\(\mu\)-term,” \(\mu H_U H_D\). This is a supersymmetric mass term for the Higgs fields. We will see later that we need \(\mu > M_Z\) to have a viable phenomenology. A set of dimension four terms permitted by the gauge symmetries raise serious issues. For example, one can have terms

\[
\bar{u}_f \bar{d}_g \bar{d}_h \Gamma^{fgh} + Q_f L_g \bar{d}_h \lambda^{fgh}.
\]  

(11.3)

These couplings violate \(B\) and \(L\)! This is our first serious setback. In the Standard Model, there is no such problem. The leading \(B\) and \(L\) violating operators permitted by gauge invariance possess dimension six, and they will be highly suppressed if
the scale of interactions which violate these symmetries is high, as in grand unified theories.

If we are not going to simply give up, we need to suppress $B$ and $L$ violation at the level of dimension-four terms. The simplest approach is to postulate additional symmetries. There are various possibilities one can imagine.

1. Global continuous symmetries. It is hard to see how such symmetries could be preserved in any quantum theory of gravity, and in string theory, there is a theorem which asserts that there are no global continuous symmetries.

2. Discrete symmetries. As we will see later, discrete symmetries can be gauge symmetries. As such, they will not be broken in a consistent quantum theory. They are common in string theory. These symmetries are often “$R$-symmetries,” symmetries which do not commute with supersymmetry.

A simple (though not unique) solution to the problem of baryon and lepton number violation by dimension-four operators is to postulate a discrete symmetry known as $R$-parity. Under this symmetry, all ordinary particles are even, while their superpartners are odd. Imposing this symmetry immediately eliminates all of the dangerous operators. For example,

$$\int d^2 \theta \bar{u} \bar{d} d \sim \psi_j \bar{\psi} \bar{d}$$ (11.4)

(we have changed notation again: the tilde here indicates the superpartner of the ordinary field, i.e. the squark) is odd under the symmetry.

More formally, we can define this symmetry as the transformation on superfields:

$$\theta_\alpha \rightarrow -\theta_\alpha$$ (11.5)

$$\begin{align*}
(Q_f, \bar{u}_f, \bar{d}_f, L_f, \bar{e}_f) &\rightarrow -(Q_f, \bar{u}_f, \bar{d}_f, L_f, \bar{e}_f) \\
(H_U, H_D) &\rightarrow (H_U, H_D).
\end{align*}$$ (11.6)

With this symmetry, the full, renormalizable superpotential is just that of Eq. (11.2).

In addition to solving the problem of very fast proton decay, $R$-parity has another striking consequence: the lightest of the new particles predicted by supersymmetry (the LSP) is stable. This particle can easily be neutral under the gauge groups. It is then, inevitably, very weakly interacting. This in turn means the following.

- The generic signature of $R$-parity conserving supersymmetric theories is events with missing energy.
- Supersymmetry is likely to produce an interesting dark-matter candidate.

This second point is one of the principal reasons that many physicists have found the possibility of low-energy supersymmetry so compelling. If one calculates the dark-matter density, as we will see in the chapter on cosmology, one
automatically finds a density in the right range if the scale of supersymmetry breaking is about 1 TeV. Later we will see an additional piece of circumstantial evidence for low-energy supersymmetry: the unification of the gauge couplings within the MSSM.

We can imagine more complicated symmetries which would have similar effects, and we will have occasion to discuss these later. In most of what follows, we will assume a conserved $Z_2$ $R$-parity.

### 11.1 Soft supersymmetry breaking in the MSSM

If supersymmetry is a feature of the underlying laws of nature, it is certainly broken. The simplest approach to model building with supersymmetry is to add soft-breaking terms to the effective Lagrangian so that the squarks, sleptons and gauginos have sufficiently large masses that they have not yet been observed (or, in the event that they are discovered, to account for their values). On the other hand, these masses shouldn’t be so large that they reintroduce the fine-tuning problem.

Without a microscopic theory of supersymmetry breaking, all of the soft terms are independent. It is interesting to ask, in the MSSM, how many soft-breaking parameters are there? More precisely, let’s count the parameters of the model beyond those of the minimal standard model with a single Higgs doublet. Having imposed $R$-parity, the number of Yukawa couplings is the same in both theories, as are the number of gauge couplings and $\theta$ parameters. The quartic couplings of the Higgs fields are completely determined in terms of the gauge couplings. So the “new” terms arise from the soft-breaking terms, as well as the $\mu$ term for the Higgs fields. We will speak loosely of all of this as the “soft-breaking” Lagrangian. Suppressing flavor indices:

$$
\mathcal{L}_{sb} = \tilde{Q}^* m_Q^2 \tilde{Q} + \tilde{u}^* m_\tilde{u}^2 \tilde{u} + \tilde{d}^* m_\tilde{d}^2 \tilde{d} + \tilde{L}^* m_L^2 \tilde{L} + \tilde{e}^* m_\tilde{e}^2 \tilde{e} + H_U \tilde{Q} A_u \tilde{u} + H_D \tilde{Q} A_d \tilde{d} + H_D \tilde{L} \tilde{A}_\ell \tilde{e} + c.c. + M_\lambda \lambda + c.c. + m_{H_U}^2 |H_U|^2 + m_{H_D}^2 |H_D|^2 + \mu B H_U H_D + \mu \psi_H \bar{\psi}_H.
$$  (11.8)

The matrices $m_Q^2$, $m_\tilde{u}^2$, and so on are $3 \times 3$ Hermitian matrices, so they have 9 independent entries. The matrices $A_u$, $A_d$, etc., are general $3 \times 3$ complex matrices, so they each possess 18 independent entries. Each of the gaugino masses is a complex number, so these introduce 6 additional parameters. The quantities $\mu$ and $B$ are also complex; this is 4 more. In total, then, there are 111 new parameters. As in the standard model, not all of these parameters are meaningful; we are free to make field redefinitions. The counting is significantly simplified if we just ask how many parameters there are beyond the usual 18 of the minimal theory, since this counting uses up most of this freedom.
To understand what redefinitions are possible beyond the transformations on the quarks and leptons which go into defining the KM parameters, we need to ask what are the symmetries of the MSSM before introducing the soft-breaking terms and the \( \mu \) term (the \( \mu \) term is more or less on the same footing as the soft-breaking terms, since it is of the same order of magnitude; as we will discuss later, it might well arise from the physics of supersymmetry breaking). Apart from the usual baryon and lepton numbers, there are two more. The first is a Peccei–Quinn symmetry, under which two Higgs superfields rotate by the same phase, while the right-handed quarks and leptons rotate by the opposite phase. The second is an \( R \)-symmetry, a generalization of the symmetry we found in the Wess–Zumino model. It is worth describing this in some detail. By definition, an \( R \)-symmetry is a symmetry of the Hamiltonian which does not commute with the supersymmetry generators. Such symmetries can be continuous or discrete. In the case of continuous \( R \)-symmetries, by convention, we can take the \( \theta \)s to transform by a phase \( e^{i\alpha} \). Then the general transformation law takes the form

\[
\lambda_i \to e^{i\alpha} \lambda_i
\]  

(11.9)

for the gauginos, while for the elements of a chiral multiplet

\[
\Phi_i(x, \theta) \to e^{ir_i\alpha} \Phi(x, \theta e^{i\alpha}),
\]

(11.10)

or, in terms of the component fields,

\[
\phi_i \to e^{ir_i\alpha} \phi_i \quad \psi_i \to e^{i(r_i-1)\alpha} \psi_i \quad F_i \to e^{i(r_i-2)\alpha} F_i.
\]

(11.11)

In order that the Lagrangian exhibit a continuous \( R \)-symmetry, the total \( R \) charge of all terms in the superpotential must be 2. In the MSSM, we can take \( r_i = 2/3 \) for all of the chiral fields.

The soft-breaking terms, in general, break two of the three lepton number symmetries, the \( R \)-symmetry and the Peccei–Quinn symmetry. So there are 4 non-trivial field redefinitions which we can perform. In addition, the minimal standard model has 2 Higgs parameters. So from our 111 parameters, we can subtract a total of 6, leaving 105 as the number of new parameters in the MSSM.

Clearly we would like to have a theory which predicts these parameters. Later, we will study some candidates. To get started, however, it is helpful to make an ansatz. The simplest thing to do is suppose that all of the scalar masses are the same, all of the gaugino masses the same, and so on. It is necessary to specify also a scale at which this Ansatz holds, since, even if true at one scale, it will not continue to hold at lower energies. Almost all investigations of supersymmetry phenomenology assume such a degeneracy at a large-energy scale, typically the reduced Planck mass, \( m_p \). It is often said that degeneracy is automatic in supergravity models, so this is frequently called the supergravity ("SUGRA") model but, as we will see,
supergravity by itself makes no prediction of degeneracy. Some authors, similarly, include this assumption as part of the definition of the MSSM, but in this text we will use this term to refer to the particle content and the renormalizable interactions. In any case, the ansatz consists of the following statements at the high-energy scale.

(1) All of the scalar masses are the same, $\tilde{m}^2 = m_0^2$. This assumption is called universality of scalar masses.
(2) The gaugino masses are the same, $M_i = M_0$. This is referred to as the “GUT” relation, since it holds in simple grand unified models.
(3) The soft-breaking cubic terms are assumed to be given by

$$L_{\text{tri}} = A(H_U Q u \bar{u} + H_D Q d \bar{d} + H_D L y_l \bar{e}).$$

(11.12)

The matrices $y_u$, $y_d$, etc., are the same matrices which appear in the Yukawa couplings. This is the assumption of proportionality.

Note that with this ansatz, if we ignore possible phases, five parameters are required to specify the model ($m_0^2$, $M_0$, $A$, $B_{\mu}$, $\mu$). One of these can be traded for $M_Z$, so this is quite an improvement in predictive power. In addition, this Ansatz automatically satisfies all constraints from rare processes. As we will explain, rare decays and flavor violation are suppressed ($b \to s + \gamma$ is not as strong a constraint, but it requires other relations among soft masses). On the other hand, we will want to ask: just how plausible are these assumptions? We will try to address this question later.

### 11.1.1 Cancellation of quadratic divergences in gauge theories

We have already seen that soft supersymmetry-violating mass terms receive only logarithmic divergences. While not essential to our present discussion, it is perhaps helpful to see how the cancellation of quadratic divergences for scalar masses arises in gauge theories like the MSSM.

Take, first, a $U(1)$ theory, with (massless) chiral fields $\phi^+$ and $\phi^-$. Before doing any computation, it is easy to see that provided we work in a way which preserves supersymmetry, there can be no quadratic divergence. In the limit that the mass term vanishes, the theory has a chiral symmetry under which $\phi^+$ and $\phi^-$ rotate by the same phase,

$$\phi^\pm \rightarrow e^{i\alpha} \phi^\pm.$$  

(11.13)

This symmetry forbids a mass term in the superpotential, $\Lambda \phi^+ \phi^-$, the only way a supersymmetric mass term could appear. The actual diagrams we need to compute are shown in Fig. 11.1. Since we are interested only in the mass, we can take the
external momentum to be zero. It is convenient to choose Landau gauge for the
gauge boson. In this gauge the gauge boson propagator is
\[
D_{\mu\nu} = -i \left( g_{\mu\nu} - \frac{q_\mu q_\nu}{q^2} \right) \frac{1}{q^2}
\] (11.14)
so the first diagram vanishes. The second, third and fourth are straightforward to
work out from the basic Lagrangian. One finds:
\[
I_b = g^2 (i) (i) \frac{3}{(2\pi)^4} \int \frac{d^4 k}{k^2},
\] (11.15)
\[
I_c = g^2 (i) (i) \left( \frac{\sqrt{2}}{2} \right)^2 \frac{1}{(2\pi)^4} \int \frac{d^4 k}{k^4} \text{tr}(k_\mu \sigma^\mu k_\nu \bar{\sigma}^\nu) \] (11.16)
\[
= -4 g^2 \frac{1}{(2\pi)^4} \int \frac{d^4 k}{k^2},
\] (11.17)
\[
I_d = g^2 (i) (i) \frac{1}{(2\pi)^4} \int \frac{d^4 k}{k^2}.
\] (11.18)

It is easy to see that the sum, \( I_a + I_b + I_c + I_d = 0 \).

Including a soft-breaking mass for the scalars, only \( I_d \) changes:
\[
I_d \rightarrow \frac{g^2}{(2\pi)^4} \int \frac{d^4 k}{k^2 - \tilde{m}^2}
\]
\[
= -i \frac{g^2}{(2\pi)^4} \int \frac{d^4 k_E}{k_E^2 + \tilde{m}^2}
\]
\[
= \tilde{m}^2_{\text{independent}} + \frac{ig^2}{16\pi^2} \tilde{m}^2 \ln(\Lambda^2/\tilde{m}^2).
\] (11.19)
We have worked here in Minkowski space, and have indicated factors of  $i$ to assist the reader in obtaining the correct signs for the diagrams. In the second line, we have performed a Wick rotation. In the third, we have separated off a mass-independent part, since we know that this is canceled by the other diagrams.

Summarizing, the one-loop mass shift is

$$\delta \tilde{m}^2 = - \frac{g^2}{16\pi^2} \tilde{m}^2 \ln(\Lambda^2 / \tilde{m}^2).$$

(11.20)

Note that the mass shift is proportional to $\tilde{m}^2$, the supersymmetry breaking mass, as we would expect since supersymmetry is restored as $\tilde{m}^2 \to 0$. In the context of the Standard Model, we see that the scale of supersymmetry breaking cannot be much larger than the Higgs mass scale itself without fine tuning. Roughly speaking, it can’t be much larger than this scale by factors of order $1/\sqrt{\alpha_W}$, i.e., factors of order six. We also see that the correction has a logarithmic sensitivity to the cutoff. So, just like the gauge and Yukawa couplings, the soft masses run with energies.

### 11.2 $SU(2) \times U(1)$ breaking

In the MSSM, there are a number of general statements which can be made about the breaking of $SU(2) \times U(1)$. The only quartic couplings of the Higgs fields arise from the $SU(2)$ and $U(1)$ $D^2$ terms. The general form of the soft-breaking mass terms has been described above. So, before worrying about any detailed Ansatz for the soft breakings, the Higgs potential is given, quite generally, by

$$V_{\text{Higgs}} = m^2_{H_U} |H_U|^2 + m^2_{H_D} |H_D|^2 - m^2_3 (H_U H_D + \text{h.c.})$$

$$+ \frac{1}{8} (g^2 + g'^2) (|H_U|^2 - |H_D|^2)^2 + \frac{1}{2} g^2 |H_U H_D|^2.$$ 

(11.21)

This potential by itself conserves CP; a simple field redefinition removes any phase in $m^2_3$. (As we will discuss shortly, there are many other possible sources of CP violation in the MSSM.) The physical states in the Higgs sector are usually described by assuming that CP is a good symmetry. In that case, there are two CP-even scalars, $H^0$ and $h^0$, where, by convention, $h^0$ is the lighter of the two. There are a CP-odd neutral scalar, $A$, and charged scalars, $H^\pm$. At tree level, one also defines a parameter

$$\tan(\beta) = \frac{|\langle H_U \rangle|}{|\langle H_D \rangle|} \equiv v_1 / v_2.$$ 

(11.22)

Note that with this definition, as $\tan(\beta)$ grows, so does the Yukawa coupling of the $b$ quark.

To obtain a suitable vacuum, there are two constraints which the soft breakings must satisfy.
Fig. 11.2. Leading contribution to Higgs production in $e^+ e^-$ annihilation.

(1) Without the soft-breaking terms, $H_U = H_D$ ($v_1 = v_2 = v$) makes the $SU(2)$ and $U(1)$ $D$ terms vanish, i.e. there is no quartic coupling in this direction. So the energy is unbounded below unless

$$m_{H_U}^2 + m_{H_D}^2 - 2|m_3|^2 > 0. \quad (11.23)$$

(2) In order to obtain symmetry breaking, the Higgs mass matrix must have a negative eigenvalue. This gives the requirement:

$$|m_3|^2 > m_{H_u}^2 m_{H_d}^2. \quad (11.24)$$

When these conditions are satisfied, it is straightforward to minimize the potential and determine the spectrum. One finds that

$$m_A^2 = \frac{m_3^2}{\sin(\beta) \cos(\beta)}. \quad (11.25)$$

It is conventional to take $m_A^2$ as one of the parameters. Then one finds that the charged Higgs masses are given by

$$m_{H^\pm}^2 = m_W^2 + m_A^2, \quad (11.26)$$

while the neutral Higgs masses are:

$$m_{H^0, h^0}^2 = \frac{1}{2} \left( m_A^2 + m_Z^2 \pm \sqrt{(m_A^2 + m_Z^2)^2 - 4m_Z^2 m_A^2 \cos(2\beta)} \right). \quad (11.27)$$

Note the inequalities:

$$m_{h^0} \leq m_A$$
$$m_{h^0} \leq m_Z$$
$$m_{H^\pm} \geq m_W. \quad (11.28)$$

The middle relation is particularly interesting since LEP II set a limit on the Higgs mass of 115 GeV. The basic process through which one searches for the Higgs in $e^+ e^-$ annihilation uses the $Z-Z-h$ vertex and exploits a virtual $Z$, to avoid using the tiny electron Yukawa coupling, as in Fig. 11.2. This limit is actually appropriate
11.3 Why is one Higgs mass negative?

Within the simple ansatz, there is a natural way to understand why $m^2_{H_U} < 0$ while $m^2_{H_D} > 0$. What is special about $H_U$ is that it has an $O(1)$ coupling to the top quark. (If $\tan(\beta)$ is very large, of order 40–50, $H_D$ has a comparable coupling to the $b$-quark). We saw earlier in the Wess–Zumino model that, at one loop, there is a negative renormalization of the soft-breaking scalar masses. This calculation can be translated to the MSSM, with a modification for the color and $SU(2)$ factors. One obtains:

$$m^2_{H_U} = (m_{H_U})^2_0 - \frac{6 y_t^2}{16 \pi^2} \ln(\Lambda^2/m^2) (\tilde{m}_t^2 + m^2_{t})$$ \hspace{1cm} (11.29)

$$\tilde{m}_t^2 = (\tilde{m}_t)^2_0 - \frac{4 y_t^2}{16 \pi^2} \ln(\Lambda^2/m^2) \tilde{m}_{H_U}^2.$$ \hspace{1cm} (11.30)

So we see that loop corrections involving the top quark Yukawa coupling reduce both the Higgs and the stop masses, but the reduction is larger for the Higgs. If $\Lambda \sim M_p$, and the typical soft breakings are of order 1 TeV, these corrections are $O(1)$, so one needs a full renormalization group analysis to determine if $SU(2) \times U(1)$ is broken. For this we need the full set of renormalization-group equations. These can be derived along the lines of the calculations we have already presented for the gauge and Yukawa contributions to the soft-mass renormalizations. If only $y_t$ is large, the one-loop expressions can be written rather compactly:

$$\mu \frac{\partial}{\partial \mu} m^2_{H_U} = \frac{1}{8 \pi^2} \left[ 3 y_t^2 (m^2_{H_U} + m^2_t + m^2_{Q_3} + |A^3_U|^2) \right] - \frac{1}{2 \pi^2} \left[ |M_2|^2 g_2^2 + |M_1|^2 g_1^2 \right]$$ \hspace{1cm} (11.31)

$$\mu \frac{\partial}{\partial \mu} m^2_t = \frac{1}{8 \pi^2} \left[ 2 y_t^2 (m^2_{H_U} + m^2_t + m^2_{Q_3} + |A^3_U|^2) \right] - \frac{1}{2 \pi^2} \left[ |M_3|^2 g_3^2 + |M_1|^2 g_1^2 \right]$$ \hspace{1cm} (11.32)

$$\mu \frac{\partial}{\partial \mu} m^2_{Q_3} = \frac{1}{8 \pi^2} \left[ 2 y_t^2 (m^2_{H_U} + m^2_t + m^2_{Q_3} + |A^3_U|^2) \right] - \frac{1}{2 \pi^2} \left[ |M_3|^2 g_3^2 + |M_2|^2 g_2^2 + |M_1|^2 g_1^2 \right].$$ \hspace{1cm} (11.33)

Two- (and in some cases higher-) loop corrections to these equations have been computed.
For scalars besides $H_U$ and the third-generation squarks one has only the contribution from diagrams involving intermediate gauginos

$$\mu \frac{\partial}{\partial \mu} m^2_i = -\frac{1}{2\pi^2} \sum_a g_a^2 |M_a|^2 c_{ai},$$

(11.34)

where $c_{ai}$ denotes the appropriate Casimir ($1/2$ for particles in the fundamental representation) while gaugino masses satisfy

$$\mu \frac{\partial}{\partial \mu} \left( \frac{M^2_a}{g_a^2} \right) = 0.$$

(11.35)

It is straightforward to integrate these equations numerically. For a significant range of parameters, one does obtain suitable breaking of $SU(2) \times U(1)$. But without analyzing these equations in great detail, one can see that, given the large value of $m_t$, there is a potential fine-tuning problem. Taking Eq. (11.30) as an approximate solution, noting that $y_t \sim 1$ (its precise value depends on $\tan(\beta)$), and allowing for the two types of quark which appear, the coefficient of the logarithm is about $1/8$. At some point, the mass of the Higgs crosses zero. If, at that point, the squark masses are, says 300 GeV$^2$, then the Higgs mass will become of order 100 GeV almost immediately. So the zero crossing must be almost exactly at the scale of the susy-breaking masses.$^1$

### 11.4 Radiative corrections to the Higgs mass limit

Despite the fact that we know $M^2_{H}$ is significantly larger than $M^2_{Z}$, this does not (as of this writing) rule out the MSSM. The actual upper limit on the Higgs mass is significantly above its tree-level value, $M_{Z}$. At tree level, the form of the Higgs potential is highly constrained. The quartic terms are exactly known. Once supersymmetry is broken, however, there can be corrections to the quartic terms from radiative corrections.$^2$ These corrections are soft, in that the susy-violating four-point functions vanish rapidly at momenta above the supersymmetry-breaking scale. Still, they are important in determining the low-energy properties of the theory, such as the Higgs vevs and the spectrum.

The largest effect of this kind comes from loops involving top quarks. It is not hard to get a rough estimate of the effect. In the limit $\tilde{m}_t \gg m_t$, the effective Lagrangian is not supersymmetric below $\tilde{m}_t$. As a result, there can be corrections to the Higgs quartic couplings. Consider the diagrams of Fig. 11.3. In this limit,

---

$^1$ This version of the fine-tuning problem was elaborated by N. Arkani-Hamed.

$^2$ In sufficiently complicated models, there can be tree-level corrections to the quartic couplings. This does not occur in the MSSM, but it can occur in models with singlets.
we can get a reasonable estimate by just keeping the top quark loop, cutting off the integral at the mass of the stop. The result will be logarithmically divergent, and we can take the cutoff to be $\tilde{m}_t$. So we have

$$\delta \lambda = (-1)y_t^4 \times 3 \int \frac{d^4 k}{(2\pi)^4} \text{Tr} \frac{1}{(k - m_t)^4}$$

$$= -\frac{12i y_t^4}{16\pi^2} \ln \left(\frac{\tilde{m}_t^2}{m_t^2}\right).$$

The implications of this result are left for the exercises at the end of this chapter.

11.5 Embedding the MSSM in supergravity

In the previous chapter, we introduced $N = 1$ supergravity theories. These theories are not renormalizable, and must be viewed as effective theories, valid below some energy scale, which might be the Planck scale or unification scale (or something else).

The approach we introduced to model building is quite useful as a model for the origin of supersymmetry breaking in the MSSM. The basic assumptions were as follows.

- The theory consists of two sets of fields, the *visible sector fields*, $y_a$, which in the context of the MSSM would be the quarks and lepton superfields, and the *hidden sector fields*, $z_i$, responsible for supersymmetry breaking.
- The superpotential was taken to have the form:

$$W(z, y) = W_z(z) + W_y(y).$$  (11.38)

- For the Kahler potential we took the simple Ansatz:

$$K = \sum_a y_a^\dagger y_a + \sum_i z_i^\dagger z_i.$$  (11.39)
In this case, we saw that if the supersymmetry-breaking scale was of order

$$M_{\text{int}} = m_3/2 M_p,$$

(11.40)

then there were an array of soft-breaking terms of order $m_3/2$. In particular, there were universal masses and $A$ terms,

$$a m_3^2 |y_a|^2 + b m_3^2 W_{ab} y_a y_b + c m_3^2 W_{abc} y_a y_b y_c.$$  

(11.41)

Here $W_{ab} = \partial_a \partial_b W$; $W_{abc} = \partial_a \partial_b \partial_c W$.

Given that the theory is at best an effective-low-energy theory, one can ask how natural are our assumptions, and what would be the consequences of relaxing them? The assumption that there is some sort of hidden sector, and that the superpotential breaks up as we have hypothesized, we will see, is a reasonable one. It can be enforced by symmetries. The assumption that the Kahler potential takes this simple (often called “minimal”) form is a strong one, not justified by symmetry considerations. It turns out not to hold, in any general sense, in string theory, the only context in which presently we can compute it. If we relax this assumption, we lose the universality of scalar masses and the proportionality of the $A$ terms to the superpotential. As we will see in the next section, without these, or something close, the MSSM is not compatible with experiment.

### 11.6 The $\mu$ term

One puzzle in the MSSM is the $\mu$ term, the supersymmetric mass term for the Higgs fields. In general, this term is not forbidden by any symmetry, so the first question is: why is it small, of order TeV rather than, say, $M_p$ or $M_{\text{gut}}$? One possibility is that there is a symmetry. Another is related to the non-renormalization theorems. If, for some reason, there is no mass term at lowest order for the Higgs fields, one will not be generated perturbatively. The $\mu$ term, then, might be the result of the same non-perturbative dynamics, for example, responsible for supersymmetry breaking. In string theories, as we will see later, it is quite common to find massless particles at tree level, simply by “accident.”

In such a situation, supersymmetry breaking can, quite easily, generate a $\mu$ term of order $m_3/2$. Consider, for example, the Polonyi model. The operator

$$\int d^4 \theta \frac{1}{M_p} Z^i H_U H_D$$

(11.42)

would generate a $\mu$ term of just the correct size. In simple grand unified theories, such a term is often generated.

When we discuss other models for supersymmetry breaking, such as gauge mediation, we will see that the $\mu$ term can be more problematic.
11.7 Constraints on soft breakings

While the number of soft-breaking parameters is large, they are subject to many experimental constraints. These come from the failure of direct searches to see superpartners of ordinary fields, and also from indirect effects.

11.7.1 Direct searches for supersymmetric particles

While have discussed limits on Higgs particles, there are many other states, and much effort has been devoted at LEP II and the Tevatron to searching for them. The limits are quite impressive. Among the states in the MSSM which are possible discovery channels for supersymmetry, are the “charginos,” linear combinations of the partners of the $W^\pm$ and $H^\pm$, and the neutralinos, linear combinations of the partners of the $Z$ and $\gamma$ ($B$ and $W^3$) and the neutral Higgs. The mass matrix for the charginos, denoted $\tilde{w}^\pm$ and $\tilde{\tilde{h}}^\pm$, is given by

$$M_{\chi^\pm} = \begin{pmatrix} M_2 & g v_1 \\ g v_2 & \mu \end{pmatrix}. \quad (11.43)$$

For the neutralinos, $w^0, b, \tilde{h}_l^0, \tilde{h}_R^0$, there is a $4 \times 4$ mass matrix. We will leave the study of these for the exercises. The lightest of these states is a natural dark matter candidate.

Direct searches at LEP II and the Tevatron strongly constrain the masses of squarks, sleptons, charginos, neutralinos and gluinos. The direct searches are easy to describe, and production and decay rates can be computed given knowledge of the spectrum, since the couplings of the fields are known. If $R$-parity is conserved, the LSP is stable and weakly interacting, so the characteristic signal for supersymmetry is missing energy. For example, in $e^+ e^-$ colliders, one can produce slepton pairs, if they are light enough, through the diagram of Fig. 11.4. These then decay, typically,
to a lepton and a neutralino, as indicated. So the final state contains a pair of acoplanar leptons, and missing energy. From such processes, one has (as of this writing) limits of order $M_Z$ or larger, for all of the charged states of the MSSM. One can obtain stronger limits – and in many cases greater discovery potential – from hadron machines. For example, because they are strongly coupled and they are octets of color, gluinos have very substantial production cross sections in hadron collisions. They can be produced both by $q\bar{q}$ and $gg$ annihilation. Gluinos can decay to a large number of channels, and many of these are used in searching for (and setting limits on) the gluino and squark masses. For example, if squarks are heavier than gluinos, gluinos decay through a diagram involving a virtual squark to a pair of quarks and a chargino or neutralino; this particle, in turn, may decay to the LSP and a pair of leptons. This is a quite distinctive signal. The limits on gluinos are greater than 200 GeV.

11.7.2 Constraints from rare processes

Rare processes provide another set of strong constraints on the soft-breaking parameters. In the simple ansatz all of the scalar masses are the same at some very-high-energy scale. However, if this is true at one scale, it is not true at all scales, i.e. these relations are renormalized. Indeed, all 105 parameters are truly parameters, and it is not obvious that the assumptions of universality and proportionality are natural. On the other hand, there are strong experimental constraints which suggest some degree of degeneracy.

As one example, there is no reason, a priori, why the mass matrix for the $\tilde{L}s$ (the partners of the lepton doublets) should be diagonal in the same basis as the charged leptons. If it is not, there is no conservation of separate lepton numbers, and the decay $\mu \rightarrow e\gamma$ will occur (Fig. 11.5). To see that we are potentially in serious trouble, we can make a crude estimate. The muon lifetime is proportional
Constraints on soft breakings

11.7 Constraints on soft breakings

181

\[ G^2 \mu m^5 \]. The decay, \( \mu \rightarrow e \gamma \) occurs due to the operator

\[ \mathcal{L}_{\mu \gamma} = e C F_{\mu \nu} \bar{u} \sigma^{\mu \nu} e. \]  

(11.44)

If there is no particular suppression, we might expect

\[ C = \frac{\alpha_w}{\pi} \frac{m_\mu}{m_{\text{susy}}^2}. \]  

(11.45)

So the ratio of these rates would be of order

\[ BR = \left( \frac{\alpha_w}{\pi} \right)^2 \left( \frac{M_W}{M_{\text{susy}}} \right)^4. \]  

(11.46)

This might be as small as \( 10^{-8} \) to \( 10^{-9} \) if the supersymmetry-breaking scale is large, 1 TeV or so. But the current experimental limit is \( 1.2 \times 10^{-11} \). So even in this case, it is necessary to suppress the off-diagonal terms. More detailed descriptions of the limits are found in the material in the suggested reading at the end of the chapter.

Another troublesome constraint arises from the neutron and electron electric dipole moments, \( d_n \) and \( d_e \). Any non-zero value of these quantities signifies CP-violation. Currently, one has \( d_n \leq 10^{-25} \text{ e cm} \), and \( d_e \leq 1.6 \times 10^{-27} \text{ e cm} \). The soft-breaking terms in the MSSM contain many new sources of CP-violation. Even with the assumptions of universality and proportionality, the gaugino mass and the \( A, \mu \) and \( B \) parameters all are complex, and can violate CP. At the quark level, the issue is that one-loop diagrams can generate a quark dipole moment, as in Fig. 11.6. Note that this particular diagram is proportional to the phases of the gluino and the \( A \) parameter. It is easy to see that even if \( m_{\text{susy}} \sim 500 \text{ GeV} \), these phases must be smaller than about \( 10^{-2} \). More detailed estimates can be found in the suggested reading at the end of the chapter.

CP is violated in the real world, so it is puzzling that all of the soft-supersymmetry-violating terms should preserve CP to such a high degree. This is in contrast to the Minimal Standard Model, with a single Higgs field, which can reproduce the observed CP-violation with phases of order 1. It is thus a serious
challenge to understand why CP should be such a good symmetry if nature is supersymmetric. Various explanations have been offered. We will discuss some of these later, but it should be kept in mind that the smallness of CP violation suggests that either the low-energy supersymmetry hypothesis is wrong, or that there is some interesting physics which explains the surprisingly small values of the dipole moments.

So far, we have discussed constraints on slepton degeneracy and CP-violating phases. There are also constraints on the squark masses arising from various flavor-violating processes. In the Standard Model, the most famous of these are strangeness changing processes, such as $K \to \bar{K}$ mixing. One of the early triumphs of the Standard Model was that it successfully explained why this mixing is so small. Indeed, the Standard Model gives a quite good estimate for the mixing. This was originally used to predict – amazingly accurately – the charmed quark mass. The mixing receives contributions from box diagrams such as the one shown in Fig. 11.7. If we consider first, only the first two generations and ignore the quark masses (compared to $M_W$), we have that

$$M(K^0 \to \bar{K}^0) \propto (V_{di} V_{is}^\dagger)(V_{sj}^\dagger V_{jd}) = 0. \quad (11.47)$$

Including fermion masses leads to terms in $L_{\text{eff}}$ of order

$$\frac{\alpha_W}{4\pi} \frac{m_c^2}{M_W^2} G_F \ln \left( \frac{m_c^2}{m_u^2} \right) (\bar{s} \gamma^\mu \gamma_5 d)(\bar{d} \gamma^\mu \gamma_5 s) + \cdots. \quad (11.48)$$

The matrix element of the operator appearing here can be estimated in various ways, and one finds that this expression roughly saturates the observed value (this was the origin of the prediction by Gaillard and Lee of the value of the charmed quark mass). Similarly, the CP-violating part (the “$\epsilon$” parameter) is in rough accord with observation, for reasonable values of the KM parameter $\delta$.

In supersymmetric theories, if squarks are degenerate, there are similar cancellations. However, if they are not, there are new, very dangerous contributions. The most serious is that indicated in Fig. 11.8, arising from exchange of gluinos.
11.7 Constraints on soft breakings

and squarks. This is nominally larger than the Standard Model contribution by a factor of \((\alpha_s/\alpha_W)^2 \approx 10\). Also, the Standard Model contribution vanishes in the chiral limit, whereas the gluino exchange does not, and this leads to an additional enhancement of nearly an order of magnitude. On the other hand, the diagram is highly suppressed in the limit of exact universality and proportionality. Proportionality means that the \(A\) terms in Eq. (11.8) are suppressed by factors of light quark masses, while universality means that the squark propagator, \(\langle \tilde{q}^* \tilde{q} \rangle\), is proportional to the unit matrix in flavor space. So there are no appreciable off-diagonal terms which can contribute to the diagram. On the other hand, there is surely some degree of non-degeneracy. One finds that even if the characteristic susy scale is 500 GeV, one needs degeneracy in the down-squark sector at the part in \(10^2\) level.

So \(K – \bar{K}\) mixing tightly constrains the down-squark mass matrix. The imaginary part provides further constraints. There are also strong limits on \(D – \bar{D}\) mixing, which significantly restrict the mass matrix in the up-squark sector. Other important constraints on soft breakings come from other rare processes, such as \(b \to s \gamma\). Again, more details can be found in the references in the suggested reading.

**Suggested reading**

The MSSM is described in most reviews of supersymmetry. Probably the best place to look for up-to-date reviews of the model and the experimental constraints is the Particle Data Group website. A useful collection of renormalization group formulas for supersymmetric theories is provided in the review by Martin and Vaughn (1994). Limits on rare processes are discussed in a number of articles, such as that by Masiero and Silvestrini (1997).

**Exercises**

1. Verify the expressions for \(I_a - I_d\) (Eqs. (11.15)–(11.18)).
2. Derive Eqs. (11.23)–(11.26).
(3) Verify the formula for the top quark corrections to the Higgs mass. Evaluate $y_t$ in terms of $m_t$ and $\sin(\beta)$. Show that, to this level of accuracy,

$$m_h^2 < m_Z^2 \cos(2\beta) + \frac{12 g^2}{16\pi^2} \frac{m_t^4}{m_W^2} \ln \left( \frac{\tilde{m}_t^2}{m_t^2} \right).$$

(4) Estimate the size of the supersymmetric contributions to the quark electric dipole moment, assuming that all of the superpartner masses are of order $m_{\text{susy}}$, and $\delta$ is a typical phase. Assuming, as well, that the neutron electric dipole moment is of order the quark electric dipole moment, how small do the phases have to be if $m_{\text{susy}} = 500$ GeV?
In this brief chapter, we discuss one of the most compelling pieces of circumstantial evidence in favor of supersymmetry: unification of coupling constants. Earlier, we introduced grand unification without supersymmetry. In this chapter, we consider how supersymmetry modifies that story.

12.1 A supersymmetric grand unified model

Just as in theories without supersymmetry, the simplest group into which one can unify the gauge group of the Standard Model is $SU(5)$. The quark and lepton superfields of a single generation again fit naturally into a $\bar{5}$ and 10.

To break $SU(5)$ to $SU(3) \times SU(2) \times U(1)$, we can again consider a 24 of Higgs fields, $\Sigma$. If we wish supersymmetry to be unbroken at high energies, the superpotential for this field should not lead to supersymmetry breaking. The simplest renormalizable superpotential is:

$$W(\Sigma) = m\text{Tr}\Sigma^2 + \frac{\lambda}{3}\text{Tr}\Sigma^3. \quad (12.1)$$

Treating this as a globally supersymmetric theory (i.e. ignoring supergravity corrections), the equations

$$\frac{\partial W}{\partial \Sigma} = 0 \quad (12.2)$$

are conveniently studied by introducing a Lagrange multiplier to enforce $\text{Tr}\Sigma = 0$. The resulting equations have three solutions:

$$\Sigma = 0; \Sigma = \frac{m}{\lambda} \text{diag}(1, 1, 1, -4); \quad \Sigma = \frac{m}{\lambda} \text{diag}(2, 2, 2, -3, -3). \quad (12.3)$$

These solutions either leave $SU(5)$ unbroken, or break $SU(5)$ to $SU(4) \times U(1)$ or to the Standard Model group. Each of these solutions is isolated; you can check
that there are no massless fields from $\Sigma$ in any of these states. At the classical level, they are degenerate.

If we include supergravity corrections, these states are split in energy. Provided the unification scale, $m$, is substantially below the Planck scale, these corrections can be treated perturbatively. In order to make the cosmological constant vanish in the $SU(3) \times SU(2) \times U(1)$ vacuum, it is necessary to include a constant in the superpotential, such that, in this vacuum, the expectation value of the superpotential is zero. As a result, the other two states have negative energy (as we will see in the chapter on gravitation, they correspond to solutions in which space-time is not Minkowski, but anti-de Sitter).

We will leave working out the details of these computations to the exercises, and turn to other features of this model. It is necessary to include Higgs fields to break $SU(2) \times U(1)$ down to $U(1)$. The simplest choice for the Higgs representation is the 5. As in the MSSM, it is actually necessary to introduce two sets of fields so as to avoid anomalies: a 5 and $\bar{5}$ are the minimal choice. We denote these fields by $H$ and $\bar{H}$.

Once again, it is important that the color triplet Higgs fields in these multiplets be massive in the $(3, 2, 1)$ vacuum. The most general renormalizable superpotential coupling the Higgs to the adjoint is:

$$m_H H \bar{H} + y \bar{H} \Sigma H.$$  \hspace{1cm} (12.4)

By carefully adjusting $y$ (or $m$), we can arrange that the Higgs doublet is massless. As a result, the triplet is automatically massive, with mass of order $m_H$. Of course, this represents an extreme fine tuning. We will see that the unification scale is about $10^{16}$ GeV, so this is a tuning of a part in $10^{13}$ or so. But it is curious that this tuning only need be done classically. Because the superpotential is not renormalized, radiative corrections do not lead to large masses for the doublets.

### 12.2 Coupling constant unification

The calculation of coupling constant unification in supersymmetric theories is quite similar to that in non-supersymmetric ones. We assume that the threshold for the supersymmetric particles is somewhere around 1 TeV. So up to that scale, we run the renormalization group equations just as in the Standard Model. Above that scale, there are new contributions from the superpartners of ordinary particles. The leading terms in the beta functions are:

$$SU(3) : b_0 = 3; \quad SU(2) : b_0 = -1; \quad U(1) : b_0 = -33/5.$$ \hspace{1cm} (12.5)

One can be more thorough, including two loop corrections and threshold effects. The result of such an analysis are shown in Fig. 12.1. One has:

$$M_{\text{gut}} = 1.2 \times 10^{16} \text{GeV}; \quad \alpha_{\text{gut}} \approx \frac{1}{25}.$$ \hspace{1cm} (12.6)
Fig. 12.1. In the Standard Model, the couplings do not unify at a point. In the MSSM, they do, provided that the threshold for new particle production is at about 1 TeV. Reprinted with permission from P. Langacker and N. Polonsky. Uncertainties in coupling constant unification. *Phys. Rev. D*, **47**, 4028 (1993). Copyright (1993) by the American Physical Society.
The agreement in the figure is striking. One can view this as a successful prediction of $\alpha_s$, given the values of the $SU(2)$ and $U(1)$ couplings.

12.3 Dimension-five operators and proton decay

We have seen that in supersymmetric theories, there are dangerous dimension four operators. These can be forbidden by a simple $Z_2$ symmetry, $R$-parity. But there are also operators of dimension five which can potentially lead to proton decay rates far larger than the experimental limits. The MSSM possesses $B$- and $L$-violating dimension-five operators which are permitted by all symmetries. For example, $R$-parity doesn’t forbid such operators as

$$\mathcal{O}_S^a = \frac{1}{M} \int d^2 \theta \bar{u} u e^+ \quad \mathcal{O}_S^b = \frac{1}{M} \int d^2 \theta QQQL. \quad (12.7)$$

These are still potentially very dangerous. When one integrates out the squarks and gauginos, they will lead to dimension-six $B$- and $L$-violating operators in the Standard Model with coefficients (optimistically) of order

$$\frac{\alpha}{4\pi} \frac{1}{M m_{\text{susy}}}. \quad (12.8)$$

Comparing with the usual minimal $SU(5)$ prediction, and supposing that $M \sim 10^{16}$ GeV, one sees that one needs a suppression of order $10^9$ or so.

Fortunately, such a suppression is quite plausible, at least in the framework of supersymmetric GUTs. In a simple $SU(5)$ model, for example, the operators of Eq. (12.7) will be generated by exchange of the color triplet partners of ordinary Higgs fields, and thus one gets two factors of Yukawa couplings. Also, in order that the operators be $SU(3)$-invariant, the color indices must be completely anti-symmetrized, so more than one generation must be involved. This suggests that suppression by factors of order Cabibbo angles is plausible. So we can readily imagine a suppression by factors of $10^{-9} - 10^{-11}$. Proton decay can be used to restrict – and does severely restrict – the parameter space of particular models. But what is quite striking is that we are automatically in the right range to be compatible with experimental constraints, and perhaps even to see something. It is not obvious that things had to be this way.

So far we have phrased this discussion in terms of baryon-violating physics at $M_{\text{gut}}$. But whatever the underlying theory at $M_p$ may be, there is no reason to think that it should preserve baryon number. So one expects that already at scales just below $M_p$, these dimension-five terms are present. If their coefficients were simply of order $1/M_p$, the proton decay rate would be enormous, five orders of magnitude or more faster than the current bounds. But in any such theory, one
must also explain the smallness of the Yukawa couplings. One popular approach is to postulate approximate symmetries. Such symmetries could well suppress the dangerous operators at the Planck scale. One might expect that there would be further suppression, in any successful underlying theory. After all, the rate from Higgs exchange in GUTs is so small because the Yukawa couplings are small. We do not really know why Yukawa couplings are small, but it is natural to suspect that this is a consequence of (approximate) symmetries. These same symmetries, if present would also suppress dimension-five operators from Planck scale sources, presumably by a comparable amount.

Finally, we mentioned earlier that one can contemplate symmetries to suppress dimension-four operators beyond a $Z_2$ $R$-parity. Such symmetries, as we will see, are common in string theory. One can write down $R$-symmetries which forbid, not only all of the dangerous dimension four operators, but some or all of the dimension-five operators as well. In this case, proton decay could be unobservable in feasible experiments.

Suggested reading

A good introduction to supersymmetric GUTs is provided in Witten (1981). The reviews and texts which we have mentioned on supersymmetry and grand unification all provide good coverage of the topic. The Particle Data Group website has an excellent survey, including up-to-date unification calculations and constraints on dimension-five operators (see Eidelman et al. 2004).

Exercises

(1) Work through the details of the simplest $SU(5)$, supersymmetric grand unified model. Solve the equations

$$\frac{\partial W}{\partial \Sigma} = 0.$$ 

Couple the system to supergravity, and determine the value of the constant in the superpotential required to cancel the cosmological constant in the $(3, 2, 1)$ minimum. Determine the resulting value of the vacuum energy in the $SU(5)$ symmetric minimum.

(2) In the simplest $SU(5)$ model, include a $5$ and $\bar{5}$ of Higgs fields. Write the most general renormalizable superpotential for these fields and the $24$, $\Sigma$. Find the condition on the parameters of the superpotential so that there is a single light doublet. Using the fact that only the Kahler potential is renormalized, show that this tuning of parameters at tree level assures that the doublet remains massless to all orders of perturbation theory.
Now consider the couplings of quarks and leptons required to generate masses for the fermions. Show that exchanges of $5$ and $\bar{5}$ Higgs lead to baryon and lepton number violating dimension-five couplings.

(3) Show how various $B$-violating four-Fermi operators are generated by squark and slepton exchange, starting with the general set of $B$- and $L$-violating terms in the superpotential.
In the previous chapter, we understood how to build realistic particle-physics models based on supersymmetry. There are already significant constraints on such theories, and experiments at the LHC will test whether these sorts of ideas are correct.

If supersymmetry is discovered, the question will become: how is supersymmetry broken? Supersymmetry breaking offers particular promise for explaining large hierarchies. Consider the non-renormalization theorems. Suppose we have a model consisting of chiral fields and gauge interactions. If the superpotential is such that supersymmetry is unbroken at tree level, the non-renormalization theorems for the superpotential which we proved in Section 9.7 guarantee that supersymmetry is not broken to all orders of perturbation theory. But they do not necessarily guarantee that effects smaller than any power of the couplings don’t break supersymmetry. So, if we denote the generic coupling constants by $g^2$, there might be effects of order, say, $e^{-c/g^2}$ which break the symmetry. In the context of a theory like the MSSM, supposing that soft breakings are of this order, this might account for the wide disparity between the weak scale (correlated with the susy-breaking scale) and the Planck or unification scale.

So one reason that the dynamics of supersymmetric theories is of interest is to understand dynamical supersymmetry breaking, and perhaps to study a whole new class of phenomena in nature. But there are other reasons to be interested, as first most clearly appreciated by Seiberg. Supersymmetric Lagrangians are far more tightly constrained than ordinary Lagrangians. It is often possible to make strong statements about dynamics which would be difficult if not impossible to study in conventional field theories. We will see this includes phenomena like electric–magnetic duality and confinement.
13.1 Criteria for supersymmetry breaking: the Witten index

We will consider a variety of theories, many of them strongly coupled. One might imagine that it is a hard problem to decide if supersymmetry is or is not broken. Even in weakly coupled theories, one might wonder whether one could establish reliably that supersymmetry is *not* broken, since, unless one solved the theory exactly, it would seem hard to assert that there was no tiny non-perturbative effect which did not break the symmetry. One of the things we will learn in this chapter is that this is not a particularly difficult problem. We will exploit several tools. One is known as the Witten index. Consider the field theory of interest in a finite box. At finite volume, the supersymmetry charges are well defined, whether or not supersymmetry is spontaneously broken. Because of the supersymmetry algebra,

\[ Q | B \rangle = \sqrt{E} | F \rangle, \quad Q | F \rangle = \sqrt{E} | B \rangle, \tag{13.1} \]

i.e. non-zero-energy states come in Fermi–Bose pairs. Zero-energy states are special; they need not be paired. In the infinite-volume limit, the question of supersymmetry breaking is the question of whether there are or are not zero-energy states. To count these, Witten suggested evaluating:

\[ \Delta = \text{Tr}(-1)^F e^{-\beta H}. \tag{13.2} \]

Non-zero-energy states do not contribute to the index. The exponential is present to provide an ultraviolet regulator: \( \Delta \) is independent of \( \beta \). More strikingly, the index is independent of all of the parameters of the theory. The only way \( \Delta \) can change as some parameter is changed is by some zero energy state acquiring non-zero energy, or a non-zero-energy state acquiring zero energy. But, because of Eq. (13.1), whenever the number of zero-energy bosonic states changes, the number of zero-energy fermionic states changes by the same amount. The index is thus topological in character, and it is from this that it derives its power, as well as its applications in a number of areas of mathematics. What can we learn from the index? If \( \Delta \neq 0 \), we can say with confidence that supersymmetry is not broken. If \( \Delta = 0 \), we don’t know.

Let’s consider an example: a supersymmetric gauge theory, with gauge group \( SU(2) \), and no chiral fields. Since \( \Delta \) is independent of parameters, we can consider the theory in a very tiny box, with very small coupling. We can evaluate \( \Delta \), somewhat heuristically, as follows. Work in \( A_0 = 0 \) gauge. Consider, first, the bosonic degrees of freedom, the \( A_i \)s, where the \( A_i \)s are matrix valued. In order for the energy to be small, we need the \( A_i \)s to be constant, and to commute. So take \( A_i \) to lie in the third dimension in the isospin space, and ignore the other bosonic degrees of freedom. One might try to remove these remaining variables by a gauge transformation, \( g = \exp(i A_i x^i) \), but \( g \) is only a sensible gauge transformation if it is single-valued,
which means that $A_i^3 = 2\pi n/L$. So $A_i^3$ is a compact variable. This reduces the problem to the quantum mechanics of a rotor. So in the lowest state the wave function is a constant. Because the $A_i^3$s are non-zero, the lowest energy states will only involve the gluinos in the 3 direction. There are two of them, $\lambda_1^3$ and $\lambda_2^3$ (again independent of coordinates).

Now recall that, in $A_0 = 0$ gauge, the states must be gauge invariant. One interesting gauge transformation is multiplication by $\sigma_2$. This flips the sign of $A^3$ and $\lambda^3$. If we assume that our Fock ground state is even under this transformation, the only invariant states are $|0\rangle$ and $\lambda_1^3\lambda_2^3|0\rangle$. So we find $\Delta = 2$. If we assume that the state is odd, then we obtain $\Delta = -2$.

As we indicated, this argument is heuristic. A more detailed, but still heuristic, argument was provided by Witten in his paper on the index. But Witten also provided a more rigorous argument, which yields the same result. For general $SU(N)$, one finds $\Delta = N$.

This already establishes that a vast array of interesting supersymmetric field theories do not break supersymmetry: not only all of the pure gauge theories, but any theory with massive matter fields. This follows from the independence of $\Delta$ of parameters. If the mass is finite, one can take it to be large; if it is sufficiently large, we can ignore the matter fields and recover the pure gauge result. Later, we will understand the dynamics of these theories in some detail, and will reproduce the result for the index. But we will also see that the limit of zero mass is subtle, and the index calculation is not directly relevant.

### 13.2 Gaugino condensation in pure gauge theories

Our goal in this section is to understand the dynamics of a pure $SU(N)$ gauge theory, with massless fermions in the adjoint representation. Without thinking about supersymmetry, one might expect the following, from our experience with real QCD.

1. The theory has a mass gap, i.e. the lowest excitations of the theory are massive.
2. Gauginos, like quarks, condense, i.e.

$$\langle \lambda \lambda \rangle = c \Lambda^3 = ce^{-(8\pi^2/\alpha g^2)}.$$  \hfill (13.3)

Note that there is no Goldstone boson associated with the gluino (gaugino) condensate. The theory has no continuous global symmetry; the classical symmetry,

$$\lambda \rightarrow e^{i\alpha} \lambda,$$  \hfill (13.4)

is anomalous. However, a discrete subgroup,

$$\lambda \rightarrow e^{2\pi i/N} \lambda,$$  \hfill (13.5)
is free of anomalies. One can see this by considering instantons in this theory. The instanton has $2N$ zero modes; this would appear to preserve a $Z_{2N}$ symmetry. But the transformation $\lambda \rightarrow -\lambda$ is actually equivalent to a Lorentz transformation (a rotation by $2\pi$). Multi-instanton solutions also preserve this symmetry, and it is believed to be exact. So the gaugino condensate breaks the $Z_N$ symmetry; there are $N$ degenerate vacua. This neatly accounts for the $N$ of the index. Later we will show that, even though the theory is strongly coupled, we can demonstrate by a controlled semiclassical computation the existence of the condensate.

Gluino condensation implies a breakdown of the non-renormalization theorems at the non-perturbative level. Recall that the Lagrangian is:

$$\mathcal{L} = \int d^2 \theta S W^2_a$$

(13.6)

so $\langle \lambda \lambda \rangle$ gives rise to a superpotential, i.e.

$$\mathcal{L} = \int d^2 \theta S \langle \lambda \lambda \rangle.$$  

(13.7)

This is our first example of a non-perturbative correction to the superpotential. Note, however, that $\langle \lambda \lambda \rangle$ depends on $S$, since it depends on $g^2$:

$$S \langle \lambda \lambda \rangle = e^{-\frac{3S}{\beta_0}}.$$  

(13.8)

So we actually have a superpotential for $S$:

$$W(S) = e^{-\frac{S}{\beta}}.$$  

(13.9)

This superpotential violates the continuous shift symmetry which we used to prove the non-renormalization theorem, but it is compatible with the non-anomalous $R$-symmetry:

$$S \rightarrow S + i \alpha N, \quad \lambda \rightarrow \lambda e^{i\alpha}.$$  

(13.10)

Under this symmetry, the superpotential transforms with charge 2.

### 13.3 Supersymmetric QCD

A rich set of theories for study are collectively referred to as “supersymmetric QCD.” These are gauge theories with gauge group $SU(N)$, $N_f$ fields, $Q_f$, in the $N$ representation, and $N_f$ fields, $\bar{Q}_f$, in the $\bar{N}$ representation. We will see that the dynamics is quite sensitive to the value of $N_f$. First consider the theory without any classical superpotential for the quarks. In this case, the theory has a large global symmetry. We can transform the $Q$s and $\bar{Q}$s by separate $SU(N)$ transformations. We can also multiply the $Q$s by a common phase, and the $\bar{Q}$s by a separate common
phase:

\[ Q_f \rightarrow e^{i\alpha} Q_f \quad \bar{Q}_f \rightarrow e^{i\beta} \bar{Q}_f. \quad (13.11) \]

Finally, the theory possesses an $R$-symmetry, under which the $Q$s and $\bar{Q}$s are neutral. In terms of component fields, under this symmetry:

\[ \psi_Q \rightarrow e^{-i\alpha} \psi_Q \quad \psi_{\bar{Q}} \rightarrow e^{-i\alpha} \psi_{\bar{Q}} \quad \lambda^a \rightarrow e^{i\alpha} \lambda^a. \quad (13.12) \]

Now consider the question of anomalies. The $SU(N)$ symmetries are free of anomalies, as is the vector-like symmetry,

\[ Q_f \rightarrow e^{i\alpha} Q_f \quad \bar{Q}_f \rightarrow e^{-i\alpha} \bar{Q}_f. \quad (13.13) \]

The $R$-symmetry, and the axial $U(1)$, are both anomalous. But we can define a non-anomalous $R$ by combining the two. The gauginos give a contribution to the anomaly proportional to $N$; so we need the fermions to carry $R$-charge $-N/N_f$. Since the bosons (and the chiral multiplets) carry $R$-charge larger by 1, we have

\[ Q_f(x, \theta) \rightarrow e^{i\alpha \frac{N_f-N}{N_f}} Q_f(x, \theta e^{-i\alpha}) \quad \bar{Q}_f(x, \theta) \rightarrow e^{i\alpha \frac{N_f-N}{N_f}} \bar{Q}_f(x, \theta e^{-i\alpha}), \quad (13.14) \]

so the symmetry of the quantum theory is $SU(N_f)_L \times SU(N_f)_R \times U(1)_R \times U(1)_V$.

We have seen that supersymmetric theories often have, classically, a large vacuum degeneracy, and this is true of this theory. In the absence of a superpotential, the potential is completely determined by the $D$ terms for the gauge fields. It is helpful to treat $D$ as a matrix-valued field,

\[ D = \sum T^a D^a. \quad (13.15) \]

As a matrix, $D$ can be expressed elegantly in terms of the scalar fields. We start with the identity:

\[ (T^a)_i^j (T^a)_k^l = \delta_i^l \delta_j^k - \frac{1}{N} \delta_i^j \delta_k^l. \quad (13.16) \]

One can derive this result a number of ways. Consider propagators for fields (like gauge bosons) in the adjoint representation of the gauge group. Take the group, first, to be $U(N)$. The propagator of the matrix-valued fields

\[ \{ A_i^j A_k^l \} \propto \delta_i^l \delta_k^j. \quad (13.17) \]

But this is the same thing as

\[ \{ A^a A^b (T^a)_i^j (T^b)_k^l \}. \quad (13.18) \]

So we obtain the identity without the $1/N$ terms. Now remembering that $A$ must be traceless, we see that we need to subtract the trace as above. (This identity
is important in understanding the $1/N$ expansion in QCD.) So a field, $\phi$, in the fundamental representation, makes a contribution:

$$\delta D_i^j = \phi_i^* \phi^j - \frac{1}{N} \delta_i^j \phi_k^* \phi^k.$$  (13.19)

In the anti-fundamental representation, the generators are $-T^a_T$ (this follows from the fact that the generators in the anti-fundamental are minus the complex conjugates of those in the fundamental, and the fact that the $T^a$s are Hermitian). So the full $D$ term is:

$$D_i^j = \sum_f Q_i^* Q^j - \tilde{Q}_i \tilde{Q}^* j - \text{Tr terms.}$$  (13.20)

In this matrix form it is not difficult to look for supersymmetric solutions, i.e. solutions of $D_i^j = 0$. A simple strategy is first to construct

$$\hat{D}_i^j = \sum_f Q_i^* Q^j - \tilde{Q}_i \tilde{Q}^* j$$  (13.21)

and demand that $\hat{D}$ either vanish or be proportional to the identity. Let’s start with the case $N_f \leq N$. For definiteness, take $N = 3$, $N_f = 2$; the general case is easy to work out. By a sequence of $SU(3)$ transformations, we can bring $Q$ to the form:

$$Q = \begin{pmatrix} v_{11} & v_{12} \\ 0 & v_{22} \\ 0 & 0 \end{pmatrix}.$$  (13.22)

By a sequence of $SU(N_f)$ transformations, we can bring this to a similar form:

$$Q = \begin{pmatrix} v_1 & 0 \\ 0 & v_2 \\ 0 & 0 \end{pmatrix}.$$  (13.23)

At this point we have used up our freedom to make further symmetry transformations on $\tilde{Q}$. But it is easy to find the most general $\tilde{Q}$ which makes the $D$ terms vanish. The contribution of $Q$ to $D_i^j$ is simply

$$D = \text{diag}(|v_1|^2, |v_2|^2).$$  (13.24)

So, in order that $D$ vanish, $\tilde{Q}$ must make an equal and opposite contribution. In order that there be no off-diagonal contributions, $\tilde{Q}$ can have entries only on the diagonal, so

$$\tilde{Q} = \begin{pmatrix} e^{i\alpha_1} v_1 & 0 \\ 0 & e^{i\alpha_2} v_2 \end{pmatrix}.$$  (13.25)
In general, in these directions, the gauge group is broken to $SU(N - N_f)$. The unbroken flavor group depends on the values of the $v_i$s. We have exhibited $N_f$ complex moduli above, but actually there are more; these are associated with the generators of the broken flavor symmetries ($SU(N_f) \times U(1)$) so there are $N_f^2 + 2N_f$ complex moduli. Note that there are $2NN_f - N_f^2$ broken gauge generators, which gain mass by “eating” the components of $Q, \bar{Q}$ that are not moduli. This leaves, of the original $2NN_f$ chiral fields, precisely $N_f^2 + 2N_f$ massless fields, so we have correctly identified the number of moduli.

Our discussion, so far, does not look gauge invariant. But this is easily, and elegantly, rectified. The moduli can be written as the gauge-invariant combinations:

$$M_f^I = \bar{Q}_f Q_f^I.$$

Expanding the fields $Q$ and $\bar{Q}$ about their expectation values gives back the explicit form for the moduli in terms of the underlying, gauge-variant fields. This feature, we will see, is quite general.

The case $N_f = N$ is similar to the case $N_f < N$, but there is a significant new feature. In addition to the flat directions with $Q = \bar{Q}$ (up to phases), the potential also vanishes if $Q = vI$, where $I$ is the identity matrix. This possibility can also be described in a gauge-invariant way, since now we have an additional pair of gauge invariant fields, which we will refer to as “baryons”:

$$B = \epsilon^{i_1...i_N} \epsilon_{a_1...a_N} Q_{i_1}^{a_1} \cdots Q_{i_N}^{a_N},$$

and similarly for $\bar{B}$.

In the case $N_f > N$, there is a larger set of baryon-like objects, corresponding to additional flat directions. We will describe them in greater detail later. Before closing this section, we should stress that, for $N_f \geq N - 1$, the gauge symmetry is completely broken. For large values of the moduli, the effective coupling of the theory is $g^2(v)$, since infrared physics cuts off at the scale of the gauge field masses. By taking $v$ as large enough that $g^2(v)$ is small, the theories can be analyzed by perturbative and semiclassical methods. Strong coupling is more challenging, but much can be understood. We will see that the dynamics naturally divides into three cases: $N_f < N$, $N_f = N$, and $N_f > N$.

### 13.4 $N_f < N$: a non-perturbative superpotential

Our problem now is to understand the dynamics of these theories. Away from the origin of the moduli spaces, this turns out to be a tractable problem. We consider first the case $N_f < N$. Suppose that the $v$s are large and roughly uniform in magnitude. Even here, we have to distinguish two cases. If $N_f = N - 1$, the gauge group is
completely broken; the low-energy dynamics consists of the set of chiral fields, $M_{f}$, $\bar{f}$. If $N_{f} < N - 1$, there is an unbroken gauge group, $SU(N - N_{f})$, with no matter fields (chiral fields) transforming under this group at low energies. The gauge theory is an asymptotically free theory, essentially like ordinary QCD with fermions in the adjoint representation. Such a theory is believed to have a mass gap, of order the scale of the theory, $\Lambda_{N-N_{f}}$. Below this scale, again, the only light fields are the moduli $M_{f}^{\dagger}$. In both cases, we can try to guess the form of the very-low-energy effective action for these fields from symmetry considerations.

We are particularly interested in whether there is a superpotential in this effective action. If not, the moduli have, exactly, no potential. In other words, even in the full quantum theory, they correspond to an exact, continuous set of ground states. What features should this superpotential possess? Most important, it should respect the flavor symmetries of the original theory (because the fields $M$ are gauge invariant, it automatically respects the gauge symmetry). Among these symmetries are the $SU(N_{f}) \times SU(N_{f})$ non-Abelian symmetry. The only invariant we can construct from $M$ is

$$\Phi = \det M.$$  \hspace{1cm} (13.28)

The determinant is invariant because it transforms under $M \to VMU$ as $\det V \det U \det M$, and, for $SU(N_{f})$ transformations, the determinant is unity. Under the baryon number symmetry, $M$ is invariant. But, under the $U(1)_{R}$ symmetry, its transformation law is more complicated:

$$\Phi \to e^{2i\alpha(N_{f}-N)}. \hspace{1cm} (13.29)$$

Under this $R$-symmetry, any would-be superpotential must transform with charge 2, so the form of the superpotential is unique:

$$W = \Lambda^{(3N-N_{f})/(N-N_{f})} \Phi^{-1/(N-N_{f})}. \hspace{1cm} (13.30)$$

Here we have inserted a factor of $\Lambda$, the scale of the theory, on dimensional grounds.

Our goal in the next two sections will be to understand the dynamical origin of this superpotential, known as the ADS (after Affleck, Dine and Seiberg) superpotential. We will see that there is a distinct difference between the cases $N_{f} = N - 1$ and $N_{f} < N - 1$. First, though, consider the case $N = N_{f}$. Then the field, $\Phi$, has $R$-charge zero, and no superpotential is possible. So no potential can be generated, perturbatively or non-perturbatively. Similarly, in the case $N_{f} > N$, we cannot construct a gauge-invariant field which is also invariant under the $SU(N_{f}) \times SU(N_{f})$ flavor symmetry. This may not be obvious, since it would seem that we could again construct $\Phi = \det(M)$. But in this case, $\Phi = 0$, by antisymmetry.

From the perspective of ordinary, non-supersymmetric field theories, what we have established here is quite surprising. Normally, we would expect that, in an
interacting theory, even if the potential vanished classically, there would be quantum corrections. For theories with $N \geq N_f$, we have just argued that this is impossible. So this is a new feature of supersymmetric theories: there are often exact moduli spaces, even at the quantum level.

In the next few sections, we will demonstrate that non-perturbative effects do indeed generate the superpotential of Eq. (13.30). The presence of the superpotential means that, at least at weak coupling (large $v$), there is no stable vacuum of the theory. At best, we can think about time-dependent, possibly cosmological, solutions. If we add a mass term for the quarks, however, we find an interesting result. If the masses are the same, we expect that all of the $v_i$'s will be the same, $v_i = v$. Suppose that the mass term is small. Then the full superpotential, at low energies, is

$$W = m \bar{Q} Q + \Lambda^{(3N-N_f)/(N-N_f)} \Phi^{-1/(N-N_f)}. \quad (13.31)$$

Remembering that $\Phi \sim v^{2N_f}$, the equation for a supersymmetric minimum has the form:

$$v^{2N/(N-N_f)} = \left(\frac{m}{\Lambda}\right) \Lambda^{2N/(N-N_f)}. \quad (13.32)$$

Note that $v$ is a complex number; this equation has $N$ roots:

$$v = e^{2\pi i k/N} \left(\frac{m}{\Lambda}\right)^{(N-N_f)/2N}. \quad (13.33)$$

What is the significance of these $N$ solutions? The mass term breaks the $SU(N_f) \times SU(N_f)$ symmetry to the vector sum. It also breaks the $U(1)_R$. But it leaves unbroken a $Z_N$ subgroup of the $U(1)$. In Eq. (13.14), $\alpha = 2N_f/N$ is a symmetry of the mass term. So these $N$ vacua are precisely those expected from breaking the $Z_N$. This $Z_N$ is the same $Z_N$ expected for a pure gauge theory, as one can see by thinking of the case where the mass of the $Q$'s and $\bar{Q}$'s is large.

### 13.4.1 The $\Lambda$-dependence of the superpotential

Previously, we proved a non-renormalization theorem for the gauge couplings by thinking of the gauge coupling itself as a background field, $S$. This relied on the shift symmetry,

$$S \rightarrow S + i\alpha.$$ 

This symmetry, however, is only a symmetry of perturbation theory. Since the imaginary part of $S, \alpha$, couples to $F \bar{F}$, instanton and other non-perturbative effects violate the symmetry. On the other hand, the theory also has an anomalous chiral symmetry, the $R$-symmetry, under which we can take all of the scalar fields to
be neutral. So the theory is symmetric under this $R$-symmetry, combined with a simultaneous shift:

$$S \rightarrow S + i(N - N_f)\alpha.$$  \hspace{1cm} (13.34)

Any superpotential must transform with charge 2 under this symmetry. The field $\Phi$ is neutral. But the $\Lambda$ parameter transforms:

$$\Lambda = e^{-\frac{8\pi^2}{3g^2}S} = e^{-\frac{8\pi^2}{3N-N_f}S}$$  \hspace{1cm} (13.35)

so

$$\Lambda^{\frac{3N-N_f}{N-N_f}} \rightarrow e^{2i\alpha} \Lambda^{\frac{3N-N_f}{N-N_f}}.$$  \hspace{1cm} (13.36)

### 13.5 The superpotential in the case $N_f < N - 1$

Consider first the case $N_f < N - 1$. At energies well below the scale $v$, the theory consists of a pure (supersymmetric) $SU(N - N_f)$ gauge theory, and a number of neutral chiral multiplets. The chiral multiplets can couple to the gauge theory only through non-renormalizable operators. Because the moduli are neutral, there are no dimension-four couplings. There are possible dimension-five couplings; they are of the form

$$\delta\phi W^2_\alpha$$  \hspace{1cm} (13.37)

where $\delta\phi$ represents the fluctuations of the moduli fields about their expectation values; the coefficient of this operator will be of order $1/v$.

We can be more precise about the form of this coupling by noting that it must respect the various symmetries, if it is written in terms of the original, unshifted fields (this is similar to our argument for the form of the superpotential). In particular, a coupling of the form:

$$\mathcal{L}_{\text{coup}} = (S + a \ln(\Phi))W^2_\alpha$$  \hspace{1cm} (13.38)

respects all of the symmetries. It clearly respects the $SU(N_f)$ symmetries. It respects the non-anomalous $U(1)_R$ symmetry as well, for a suitable choice of $a$, since

$$\ln(\Phi) \rightarrow \ln(\Phi) + (N - N_f)/N_f\alpha.$$  \hspace{1cm} (13.39)

It is not hard to see how this coupling is generated.

$$\Phi \approx v^N + v^{N-1}\phi.$$  \hspace{1cm} (13.40)

Im $\phi$ couples to $F\tilde{F}$ through the anomaly diagram, just like an axion. The real part couples to $F^2$. One can see this by a direct calculation, or by noting that the masses of the heavy fields are proportional to $v$, so the gauge coupling of the $SU(N - N_f)$
13.6 \( N_f = N - 1 \): the instanton-generated superpotential

In the case \( N_f = N - 1 \), the superpotential is generated by a different mechanism: instantons. Before describing the actual computation, we give some circumstantial evidence for this fact. Consider the instanton action. This is

\[
e^{-\frac{8\pi^2}{g^2}}.
\]

(13.43)

Here we have assumed that the coupling is to be evaluated at the scale of the scalar vevs. The gauge group is, after all, completely broken, so provided that the computation is finite, this is the only relevant scale (we are also assuming that all of the vevs are of the same order). So any superpotential we might compute behaves as

\[
W \sim v^3 \left( \frac{\Lambda}{v} \right)^{2N+1} \sim \frac{\Lambda^{2N+1}}{v^{2N-2}},
\]

(13.44)

which is the behavior predicted by the symmetry arguments.

To actually compute the instanton contribution to the superpotential, we need to develop further than in Chapter 5 the instanton computation and the structure of the supersymmetry zero modes. The required techniques were developed by ’t Hooft, when he computed the baryon-number-violating terms in the effective action of the standard model; ’t Hooft started by noting that, in the presence of the Higgs field, there is no instanton solution. This can be seen by a simple scaling argument. The instanton solution will now involve \( A^\mu \) and \( \phi \). Suppose one has such a solution. Now simply do a rescaling of all lengths:

\[
x^\mu \to \rho x^\mu, \quad A^\mu \to \frac{1}{\rho} A^\mu, \quad \phi \to \phi
\]

(13.45)
(because $\phi$ must tend to its expectation value at $\infty$, we cannot rescale it). Then the gauge kinetic terms are invariant, but the scalar kinetic terms are not; $|D\phi|^2 \rightarrow \rho^2|D\phi|^2$. So the action is changed, and there is no solution.

However, the instanton configuration, while not a solution, is still distinguished by its topology; ’t Hooft argued that it makes sense to integrate over solutions of a given topology. This just means that we write a configuration for each value of $\rho$, and integrate over $\rho$. For small $\rho$, we can understand this in the following way. The non-zero modes of the instanton, before turning on the scalar vevs, all have eigenvalues of order $1/\rho$ or larger, and can be ignored. There are also zero modes. Those associated with rotations and translations will remain at zero, even in the presence of the scalar, since they correspond to exact symmetries. But this is not the case for the dilatational zero mode; this mode is slightly lifted. The scaling argument above shows that the action is smallest at small $\rho$; we will see in a moment that the action of the interesting configurations vanishes as $\rho \rightarrow 0$. We know from our earlier studies of QCD, on the other hand, that the renormalization of the coupling tends to make the action large at small $\rho$. Together, these effects yield a minimum of the action at small, finite $\rho$, giving a self-consistent justification of the approximation.

To proceed with the computation, we review ’t Hooft’s notation for the instanton. Recall that the instanton preserves an $SU(2)$, which is a combination of rotations and gauge transformations. Since the instanton solution is a Euclidean solution, the original spatial symmetry is $O(4)$, so it is valuable to understand how the rotational $SU(2)$ is embedded in this group. More precisely, $SU(2) \times SU(2) \subset O(4)$. Our two-component notation is convenient for this. After the rotation to Euclidean space, we can write the matrices $\sigma^\mu$ and $\bar{\sigma}^\mu$ as

$$\sigma^\mu = (i, \bar{\sigma}) \quad \bar{\sigma}^\mu = (i, -\bar{\sigma}). \quad (13.46)$$

The $O(4)$ generators are:

$$\begin{align*}
\sigma^{4i} &= \sigma^i \\
\bar{\sigma}^{4i} &= -\sigma^i \\
\sigma^{ij} &= \epsilon_{ijk}\sigma^k \\
\bar{\sigma}^{ij} &= -\epsilon_{ijk}\sigma^k.
\end{align*} \quad (13.47)$$

Note we have separated out the indices 4 and $i$. The matrices $\sigma^{\mu\nu}$ and $\bar{\sigma}^{\mu\nu}$ are self-dual and anti-self-dual respectively, as can be seen from these equations.

Then ’t Hooft introduced a symbol, $\eta_{a\mu\nu} = 1/2 \text{Tr} (\sigma^a \sigma^{\mu\nu})$, and a similar symbol $\bar{\eta}$. These symbols are self-dual and anti-self-dual, and define an embedding of the two $SU(2)$ subgroups. The detailed components are:

$$\eta_{a\mu\nu} = \epsilon_{a\mu\nu} \text{ if } \mu, \nu = 1, 2, 3 \quad \eta_{a44} = -\delta_{a4} \quad \eta_{a4\nu} = -\delta_{a\nu} \quad \eta_{a\mu4} = \delta_{a\mu} \quad \eta_{a44} = 0. \quad (13.48)$$

Note that $\bar{\eta}$ differs by:

$$\bar{\eta}_{a\mu\nu} = (-1)^{\delta_{a4} + \delta_{\mu4}} \eta_{a\mu\nu} \quad (13.49)$$
Also, $\eta$ has the properties:

$$
\eta_{a\mu\nu} = -\eta_{\mu a\nu} \quad \eta_{a\mu\nu} = \frac{1}{2} \epsilon_{\mu\nu a\beta} \eta_{a\alpha\beta}
$$

(13.50)

In terms of $\eta$, the instanton solution is:

$$
A^a_\mu(x) = \frac{2 \eta_{a\mu\nu} x_\nu}{(x^2 + \rho^2)}.
$$

(13.51)

It is straightforward to work out $F_{\mu\nu}$ (see the exercises):

$$
F^a_{\mu\nu} = \frac{\eta_{a\mu\nu}}{(x^2 + \rho^2)^2}.
$$

(13.52)

$F$ is self-dual, since $\eta$ is, so this is a solution of the Euclidean equations.

A second-rank antisymmetric tensor ($F_{\mu\nu}$) is a six-dimensional representation of $SO(4)$; under $SU(2) \times SU(2)$, it decomposes as a $(3, 1) + (1, 3)$, where these are the self-dual and anti-self-dual parts of the tensor. The $\eta$ symbol is essentially a Clebsch–Gordan coefficient, which describes a mapping of one $SU(2)$ subgroup of $SO(4)$ into $SU(2)$. Other important properties of these symbols include

$$
\epsilon_{abc} \eta_{b\mu\nu} \eta_{c\kappa\lambda} = \delta_{\mu\kappa} \eta_{a\nu\lambda} - \delta_{\mu\lambda} \eta_{a\nu\kappa} - \delta_{\nu\kappa} \eta_{a\mu\lambda} + \delta_{\nu\lambda} \eta_{a\mu\kappa}.
$$

(13.53)

At large distances, the instanton is a gauge transformation of “nothing.” The gauge transformation is just

$$
g^i_j = i \tilde{\sigma}^\mu_i \bar{x}^\mu.
$$

(13.54)

This can be thought of as a mapping of $S_3$ into $SU(2)$; the winding number of the instanton just counts the number of times space is mapped onto the group.

In this form, it is useful to note another way to describe the instanton solution.

By an inversion of coordinates, one can write:

$$
A^a_\mu = \frac{2}{g^2 (x^2 + \rho^2)} \eta_{a\mu\nu} \frac{x^\nu}{x^2}.
$$

(13.55)

This singular gauge instanton is often useful since it falls off more rapidly at large $x$ than the original instanton solution.

Now for the doublets we solve the equation:

$$
D^2 Q = D^2 \bar{Q} = 0.
$$

(13.56)

This has the solutions

$$
Q^i = \bar{Q}^i = i \tilde{\sigma}^\mu_i x^\mu \left( \frac{1}{x^2 + \rho^2} \right)^{1/2} (Q^j),
$$

(13.57)
and similarly for $\bar{Q}$. Like the solution for $A^\mu$, these solutions are “pure gauge” configurations as $r \to \infty$, i.e. they are gauge transformations by $g$ of the constant vev. (Note here and above, the $\sigma^\mu$s are the Euclidean versions of the two-component Dirac matrices, $\sigma^\mu = (i, \vec{\sigma}), \bar{\sigma}^\mu = (i, -\vec{\sigma})$.)

The action of this configuration is:

$$S(\rho) = \frac{1}{g^2} (8\pi^2 + 4\pi^2 \rho^2 v^2). \quad (13.58)$$

Some features of this result are worth noting.

1. The integral over $\rho$ now converges for large $\rho$, since it is exponentially damped.
2. Terms in the potential, involving $|Q|^4$, make smaller contributions to the action, by powers of $\rho$. Rescaling $x \to \rho x$, one sees that these terms are of order $\rho^4$. But $\rho$ is at most of order $g v^{-1} = m_w$ (item (1) above), so these terms are suppressed. This justifies our neglect of these terms in the equations of motion.

Our goal is to compute the instanton contribution to the effective action. We particularly want to see if the instanton generates the conjectured non-perturbative superpotential. In order to compute the effective action, we need to ask about the fermion zero modes. Before turning on the vevs for the scalars, there are six zero modes. Two of these are generated by supersymmetry transformations of the instanton solution:

$$\delta \lambda = \sigma^\mu^\nu \beta F^\mu^\nu \epsilon_\beta \quad (13.59)$$

so

$$\lambda_{^a}^{^a \alpha \lambda [^\beta]} = \frac{8\sigma^\mu^\nu \beta a}{(x^2 + \rho^2)^2}. \quad (13.60)$$

Note that, because of the anti-self-duality of $\bar{\sigma}^\mu$, two of the supersymmetry generators annihilate the lowest-order solution, i.e. there are only two supersymmetry zero modes. If we neglect the Higgs, the classical Yang–Mills action has a conformal (scale) symmetry. This is the origin of the $\rho$ zero mode in the classical solution. In the supersymmetric case, there is, apart from supersymmetry, an additional fermionic symmetry called superconformal invariance. In superspace, the corresponding generators are

$$Q^{^{SC}} = \chi Q \quad (13.61)$$

so

$$\lambda_{^\alpha}^{^{SC} ^a [^\beta]} = \frac{8 \chi \sigma^\mu^\nu \beta a}{(x^2 + \rho^2)^2}. \quad (13.62)$$
There are also two matter-field zero modes, one for each of the quark doublets:

\[ \psi^i_Q \alpha = \frac{\delta^i_\alpha}{(x^2 + \rho^2)^{3/2}} = \psi_{\bar{Q}} \]  

(in the last equation we are treating \( \bar{Q} \) also as a doublet; one can treat this as a \( 2^* \) representation by multiplying by \( \epsilon_{ij} \)).

When we turn on the scalar vevs, these modes are corrected. The superconformal symmetry is broken by these vevs and, not surprisingly, the superconformal zero modes are lifted. In fact, they pair with the two quark zero modes. We can compute this pairing by treating the Yukawa terms in the Lagrangian as a perturbation, replacing the scalar fields by their classical values. Expanding to second order, i.e. including

\[ \int d^4x Q^* \psi_Q \lambda \int d^4x' \bar{Q}^* \psi_{\bar{Q}} \lambda \]  

and expanding the fields in the lowest-order eigenmodes, the superconformal and matter-field zero modes can be absorbed by these terms. Note, in particular, that both \( Q_{cl} \) and \( \lambda^{SC} \) are odd under \( x \rightarrow -x \), while the matter-field zero modes are even, so the integral is non-zero. The supersymmetry zero modes, being even, cannot be soaked up in this way.

The wave functions of the supersymmetry zero modes are altered in the presence of the Higgs fields, and they now have components in the \( \psi_Q^* \) and \( \psi_{\bar{Q}}^* \) directions. For \( \psi_Q \), for example, we need to solve the equation

\[ D_\mu \bar{\sigma}^\mu \psi_Q^{SS} = \lambda^{SS} Q^*. \]  

But this equation is easy to solve, starting with our solution of the scalar equation. If we simply take:

\[ \psi_Q^{SS} = D_\mu \sigma^\mu Q^*, \]  

plugging back in, the left-hand side becomes

\[ D^2 Q + \sigma_{\mu \nu} F^{\mu \nu} Q, \]  

but the first term vanishes on the classical solution, while the second is, indeed, just \( \lambda^{SS} Q^* \).

With these ingredients, we can compute the superpotential terms in the effective action. In particular, the non-perturbative superpotential predicts a non-zero term in the component form of the effective action proportional to:

\[ \frac{\partial^2 W}{\partial Q \partial \bar{Q}} = \frac{1}{v^4} \psi_Q \psi_{\bar{Q}}. \]
We can calculate this term by studying the corresponding Green function. We need to be careful, now, about the various collective coordinates. We want to study the gauge-invariant correlation function

\[ \langle \bar{Q}(x)\psi_Q(x)\psi_{\bar{Q}}(y)Q(y) \rangle \quad (13.69) \]

in the presence of the instanton. Since we are interested in the low-momentum limit of the effective action, we can take \( x \) and \( y \) to be widely separated. We need to integrate over the instanton location, \( x_0 \), and the instanton orientation and scale size. Because the gauge fields are massive, we can take \( x \) and \( y \) both to be far away from the instanton. Then, from our explicit solution for the supersymmetry zero modes

\[ \psi_Q(x) \propto \mathcal{D} Q \propto \mathcal{D} \frac{i \sigma^\mu (x^\mu - x_0^\mu)}{((x - x_0)^2 + \rho^2)^{1/2}} \rightarrow g(x - x_0) S_F(x - x_0), \quad (13.70) \]

with a similar equation for \( \psi_{\bar{Q}} \). The \( g \) and \( g^\dagger \) factors are canceled by corresponding factors in \( Q \) and \( \bar{Q} \), at large distances. Substituting these expressions into the path integral and integrating over \( x_0 \) gives a convolution, \( v^2 \int d^4 x_0 S_F(x - x_0) S_F(y - y_0) \). Extracting the external propagators, we obtain the effective action. Integrating over \( \rho \) gives a term of precisely the desired form. If we contract the gauge and spinor indices in a gauge- and rotationally invariant manner, the integral over rotations just gives a constant factor. It is some work to do all of the bookkeeping correctly. The evaluation of the determinant is greatly facilitated by supersymmetry: there is a precise fermion–boson pairing of all of the non-zero modes. In the exercises, you are asked to work out more details of this computation; further details can also be found in the References.

Without working through all of the details we can see the main features.

1. The perturbative lifting of the zero modes gives rise to a contribution proportional to \( v^2 \) (see Fig. 13.1).
2. The matter-field component of the supersymmetry zero modes studied above gives a contribution to the gauge-invariant correlation function:

\[ v^4 \int d^4 x_0 S_F(x - x_0) S_F(y - y_0) \quad (13.71) \]

3. The integral over the gauge collective coordinates (equivalently the rotational collective coordinates) simply gives a constant, since we have computed a gauge- and rotationally invariant quantity.
4. The scale size collective coordinate integral behaves as

\[ W = A \int d\rho v^4 e^{-\left(\frac{\rho^2}{4\pi^2} + 4\pi^2 \rho^2 v^2\right)} \quad (13.72) \]
where the power of $\rho$ has been determined from dimensional analysis, and $A$ is a constant.

(5) Extracting the constant requires careful attention to the normalization of the zero modes and to the Jacobians for the collective coordinates. However, the non-zero modes come in Fermi–Bose pairs, and their contribution to the functional integral cancels.

(6) The final $\rho$ integral gives

$$W = A \frac{\Lambda^5}{v^2}$$

consistent with the expectations of the symmetry analysis.

This analysis generalizes straightforwardly to the case of general $N_c$.

### 13.6.1 An application of the instanton result: gaugino condensation

The instanton calculation for the case $N_f = N - 1$ is a systematic, weak-coupling computation of the superpotential which appears in the low-energy-effective action. Seiberg has noted that this result, plus holomorphy, allows systematic study of the strongly coupled regime of other theories. To understand this, take $N = 2$, and add a mass term for the quark. In this case, for very small mass, the superpotential is:

$$W = m \bar{Q} Q + \frac{\Lambda^{2N+1}}{\bar{Q} Q}.$$
We can solve the equation for $Q$, 

$$Q_1 = \begin{pmatrix} 0 \\ v \end{pmatrix} \quad v = \left( \frac{\Lambda^5}{m} \right)^{1/4}.$$  \hspace{1cm} (13.75)

Using this, we can evaluate the expectation value of the superpotential at the minimum:

$$W(m, \Lambda) = \Lambda^{5/2} m^{1/2}.$$  \hspace{1cm} (13.76)

Because $W$ is holomorphic, this result also holds for large $m$. For large $m$, the low-energy theory is just a pure $SU(2)$ gauge theory. We expect, there, that the superpotential is $\langle \lambda \lambda \rangle = \Lambda^3_{\text{le}}$. But this is equal to:

$$W = \langle \lambda \lambda \rangle = m^3 e^{-\frac{8\pi^2}{2g^2(m)}}.$$  \hspace{1cm} (13.77)

The right-hand side is nothing but $\Lambda^3_{\text{le}}$. We have, in fact, done a systematic, reliable computation of the gluino condensate in a strongly interacting gauge theory!

**Suggested reading**

Excellent treatments of supersymmetric dynamics appear in the text by Weinberg (1995), and in Michael Peskin’s lectures (1997). We have already mentioned ’t Hooft’s original instanton paper (1976). The instanton computation of the superpotential is described in Affleck *et al.* (1984).

**Exercises**

1. Verify that $\sigma_{\mu\nu}$ and $\bar{\sigma}_{\mu\nu}$ are self-dual and anti-self-dual, respectively. This means $\text{Tr} \sigma^a \sigma_{\mu\nu}$ is a self-dual tensor. Verify the connection to $\eta$; do the same thing for $\bar{\eta}$.
2. Verify Eq. (13.52), so $F$ is self-dual, and so solves the Euclidean Yang–Mills equations. Check that asymptotically the instanton potential is a gauge transform of “nothing.”
3. Verify the solution of the scalar field equation (Eq. (13.57)). Compute the action of this field configuration.
4. Do the zero-mode counting for the case of general $N_c$, $N_f = N_c - 1$. Show that, again, all but two zero modes pair with matter-field zero modes; two supersymmetry zero modes contain matter-field components which can give rise to the expected superpotential.
One of the original reasons for interest in supersymmetry was the possibility of dynamical supersymmetry breaking. So far, however, we have exhibited models in which supersymmetry is unbroken, as in the case of QCD with only massive quarks, or models with moduli spaces or approximate moduli spaces. In this section, we describe a number of models in which non-trivial dynamics breaks supersymmetry. We will see that the dynamical supersymmetry breaking occurs under special, but readily understood, conditions. In some cases, we will be able to exhibit this breaking explicitly, through systematic calculations. In others, we will have to invoke more general arguments.

14.1 Models of dynamical supersymmetry breaking

We might ask why, so far, we have not found supersymmetry to be dynamically broken. In supersymmetric QCD with massive quarks, we might give the index as an explanation. We might also note that there is not a promising candidate for a goldstino. With massless quarks, we have flat directions, and as the fields get larger, the theory becomes more weakly coupled, so any potential tends to zero.

This suggests two criteria for finding models with dynamical supersymmetry breaking.

(1) The theory should have no flat directions at the classical level.
(2) The theory should have a spontaneously broken global symmetry.

The second criterion implies the existence of a Goldstone boson. If supersymmetry is unbroken, any would-be Goldstone boson must lie in a multiplet with another scalar, as well as a Weyl fermion. This other scalar, like the Goldstone particle, has no potential, so the theory has a flat direction. But by assumption, the theory classically (and therefore almost certainly quantum mechanically) has no flat direction.
So supersymmetry is likely to be broken. These criteria are heuristic but, in practice, when a systematic analysis is possible, they are always correct.

Perhaps the simplest model with these features is a supersymmetric $SU(5)$ theory with a single $\tilde{5}$ and $10$. In the Exercises, you will show that this theory, in fact, has no flat directions, and that it has two non-anomalous $U(1)$ symmetries. One can give arguments that these symmetries are broken. So it is likely that this theory breaks supersymmetry.

However, this is a strongly coupled model, and it is difficult to prove that supersymmetry is broken. In the next section, we will describe a simple weakly coupled theory in which dynamical supersymmetry breaking occurs within a controlled approximation.

### 14.1.1 The (3, 2) model

A model in which supersymmetry turns out to be broken is the “3–2 model.” This theory has gauge symmetry $SU(3) \times SU(2)$, and matter content:

$$Q(3, 2) \quad \bar{U}(\bar{3}, 1) \quad L(1, 2) \quad \bar{D}(\bar{3}, 1). \quad (14.1)$$

This is similar to the field content of a single generation of the standard model, without the extra $U(1)$ and the positron. The most general renormalizable superpotential consistent with the symmetries is

$$W = \lambda QL\bar{U}. \quad (14.2)$$

This model admits an $R$-symmetry that is free of anomalies. There is also a conventional $U(1)$ symmetry, under which the charges of the various fields are the same as in the standard model (one can gauge this symmetry if one also adds an $e^+$ field).

While this model has global symmetries, it is different from supersymmetric QCD in that it does not have classical flat directions. To see this, note that by $SU(3) \times SU(2)$ transformations, one can bring $Q$ to the form

$$Q = \begin{pmatrix} a & 0 \\ 0 & b \\ 0 & 0 \end{pmatrix}. \quad (14.3)$$

Now the vanishing of the $SU(2) D$ term forces

$$L = \left(0, \sqrt{|a^2| - |b^2|}\right). \quad (14.4)$$

The vanishing of the $F$ terms for $\bar{u}$ require $|a| = |b|$. Then the vanishing of the $SU(3) D$ term forces

$$\bar{U} = \begin{pmatrix} a' \\ 0 \\ 0 \end{pmatrix}, \quad \bar{D} = \begin{pmatrix} 0 \\ a'' \\ 0 \end{pmatrix}. \quad (14.5)$$
(up to interchange of the two vevs), with

$$|a'| = |a''| = |a|.$$  

Finally, the $\partial W/\partial L$ equations lead to $a = 0$.

To analyze the dynamics of this theory, consider first the case that $\Lambda_3 \gg \Lambda_2$. Ignoring, at first, the superpotential term, this is just $SU(3)$ with two flavors. In the flat direction of the $D$ terms, there is a non-perturbative superpotential,

$$W_{np} = \frac{\Lambda^5}{\det Q \bar{Q}} \sim \frac{1}{v^4}. \quad (14.6)$$

The full superpotential in the low-energy theory is a sum of this term and the perturbative term. It is straightforward to minimize the potential, and establish that supersymmetry is broken. One finds

$$a = 1.287\Lambda/\lambda^{1/7} \quad b = 1.249\Lambda/\lambda^{1/7} \quad E = 3.593\lambda^{10/7} \Lambda^4. \quad (14.7)$$

If $\Lambda_2 \gg \Lambda_3$, supersymmetry is still broken, but the mechanism is different. In this case, before including the classical superpotential, the strongly coupled theory is $SU(2)$ with two flavors. This is an example of a model with a quantum moduli space. This notion will be explained in the next chapter, but it implies that $\langle QL \rangle \neq 0$, so at low energies there is a superpotential ($F$-term) for $\bar{U}$.

There does not, at the present time, exist an algorithm to generate all models which exhibit dynamical supersymmetry breaking, but many classes are known. A generalization of the $SU(5)$ model, for example, is provided by an $SU(N)$ model with an antisymmetric tensor field, $A_{ij}$, and $N - 4$ $\bar{F}$s. It is also necessary to include a superpotential,

$$W = \lambda_{ab} A \bar{F}^a \bar{F}^b. \quad (14.8)$$

Other broad classes are known, including generalizations of the $(3, 2)$ model. A somewhat different, and particularly interesting set of models, is described in Section 15.4. Catalogs of known models, as well as studies of their dynamics, are given in some of the references in the Suggested reading at the end of this chapter.

We have seen, in this section, that dynamical breaking of supersymmetry is common. Flat directions are often lifted, and in many instances, supersymmetry is broken with a stable ground state. So we are ready to address the question: how might supersymmetry be broken in the real world?

### 14.2 Particle physics and dynamical supersymmetry breaking

#### 14.2.1 Gravity mediation and dynamical supersymmetry breaking: anomaly mediation

One simple approach to model building which we explored in Chapter 11 was to treat a theory which breaks supersymmetry as a “hidden sector.” This construction,
as we presented it, was rather artificial. If we replace, say, the Polonyi sector, by a sector which breaks supersymmetry dynamically, the situation is dramatically improved. If we suppose that there are some fields transforming under only the Standard Model gauge group, and some transforming under only the gauge group responsible for symmetry breaking, the visible/hidden sector division is automatic. As we will see, this sort of division can arise rather naturally in string theory.

In such an approach the scale of supersymmetry breaking is again $m_{3/2} \cdot M_{\text{P}}$, where we now understand this scale as arising as the exponential of a small coupling at a high-energy scale (presumably the Planck, GUT, or string scale). For scalars, soft-supersymmetry-breaking masses and couplings arise just as they did previously. There is no symmetry reason why these masses should exhibit any sort of universality.

One puzzle in this scenario is related to gluino masses. Examining the supergravity Lagrangian, the only terms which can lead to gaugino masses are

$$L_{\lambda \lambda} = e^{K/2} f'_{\alpha \beta \kappa} (D_k W) \lambda^\alpha \lambda^\beta.$$  (14.9)

Here $f$ is the gauge coupling function. So in order to obtain a substantial gaugino mass, it is necessary that there be gauge-single fields with non-zero $F$ terms. In most models of dynamical supersymmetry breaking, there are no scalars which are singlets under all of the gauge interactions. Even when there are, it is necessary to suppose that there is some sort of discrete symmetry which accounts for the absence of certain couplings. These symmetries will forbid coupling of hidden sector fields to visible sector gauge fields through low-dimension operators. In other words, we don’t have couplings of the form

$$\frac{S}{M} W^2 \alpha^a$$  (14.10)

where the $F$ component of $S$ has a non-zero vev. This suggests that gaugino masses would be suppressed relative to squark and slepton masses by powers of $M_{\text{int}}/M_{\text{P}}$.

But this turns out not to be quite correct; gaugino masses, in supergravity theories, can arise as a result of certain anomalous behavior. Suppose that the low-energy gauge group is just that of the Standard Model, and that there is some very massive field, $\Sigma$, say an octet of $SU(3)$. The $\Sigma$ superpotential might take the form:

$$W_{\Sigma} = \frac{M_{\Sigma}}{2} \Sigma^a \Sigma^a.$$  (14.11)

As a result of supersymmetry breaking, there will in general be a term in the potential for the $\Sigma$ scalars:

$$V_B(\Sigma) = b m_{3/2} M_{\Sigma} \Sigma^2 + \text{c.c.}$$  (14.12)
As a result, there is a one-loop contribution to the *gluino* masses upon integrating out the $\Sigma$ field, as in Fig. 14.1. This contribution is of order $b(\alpha_s/\pi)m_{3/2}$. But we have just argued that there can be no such term from a supersymmetric effective action.

There is a simple resolution to this paradox. The puzzling contribution to the gaugino mass is independent of $M$. Suppose, then, we “regulated” this finite diagram with a Pauli–Villars regulator field. Then the gaugino mass would vanish, as expected from symmetry arguments, and the paradox would seem to disappear.

But now we have a different problem. Suppose, for a moment, that the light squark fields were also vector-like. Then we might expect that we would have to regulate these with Pauli–Villars fields as well. But then, these Pauli–Villars fields *would* give contributions to gaugino masses, of order $(\alpha_s/\pi)m_{3/2}$. In fact, we would obtain:

$$m_{\lambda_i} = b_0 \frac{\alpha_i}{\pi} m_{3/2},$$

(14.13)

where $b_0$ is the one-loop beta function. This mechanism for generating gaugino masses is known as *anomaly mediation*.

In the framework we have described, there is no reason to expect that the leading contribution to scalar masses should vanish. But one might speculate that this could occur in some circumstances. If it does, and if the one-loop contributions to scalar masses vanish as well, there are two-loop contributions, analogous to those we have found above. They can be obtained by a similar analysis. The result is proportional to two powers of the couplings, $\alpha_i$, and the beta functions. At one level, this formula is quite appealing. It appears highly predictive. It is also universal, so flavor changing processes are suppressed. It is also, unfortunately, phenomenologically unsuccessful, as it predicts tachyonic masses for slepton doublets.

To build models along these lines, then, two ingredients are required. First, one must explain why there are almost no contributions to scalar masses as large as these
two-loop effects. Then one must explain why there are some which can give larger masses to the lepton doublets. The first turns out to be problematic. In string theory and in certain large extra dimension models, the leading-order Kahler potential is often of a special form which can give vanishing scalar masses even in the presence of hidden sector supersymmetry breaking. But in these situations, there are corrections to the Kahler potential which usually swamp the anomalous two-loop contributions.

### 14.2.2 Low-energy dynamical supersymmetry breaking: gauge mediation

An alternative to the conventional supergravity approach is to suppose that supersymmetry is broken at some much-lower energy, with gauge interactions serving as the messengers of supersymmetry breaking. The basic idea is simple. One again supposes that one has some set of new fields and interactions which break supersymmetry. Some of these fields are taken to carry ordinary Standard Model quantum numbers, so that “ordinary” squarks, sleptons and gauginos can couple to them through gauge loops. This approach, which is referred to as “gauge mediated supersymmetry breaking” (GMSB), has a number of virtues.

1. It is highly predictive: as few as two parameters describe all soft breakings.
2. The degeneracies required to suppress flavor-changing neutral currents are automatic.
3. GMSB easily incorporates DSB, and so can readily explain the hierarchy.
4. GMSB makes dramatic and distinctive experimental predictions.

The approach, however, also has drawbacks. Perhaps most serious is related to the “$\mu$ problem,” which we discussed in the MSSM. In theories with high-scale-supersymmetry breaking, we saw that there is not really a problem at all; a $\mu$ term of order the weak scale is quite natural. The $\mu$ problem, however, finds a home in the framework of low-energy breaking. The difficulty is that, if one is trying to explain the weak scale dynamically, one does not want to introduce the $\mu$ term by hand. Various solutions have been offered for this problem, but none is yet compelling. In the rest of our discussion, we will simply assume that a $\mu$ term has been generated in the effective theory, and not worry about its origin.

**Minimal Gauge Mediation (MGM)**

The simplest model of gauge mediation contains, as messengers, a vector-like set of quarks and leptons, $q, \bar{q}, \ell, \bar{\ell}$. These have the quantum numbers of a 5 and $\bar{5}$ of $SU(5)$. The superpotential is taken to be

$$W_{\text{mgm}} = \lambda_1 q \bar{q} + \lambda_2 S \ell \bar{\ell}. \quad (14.14)$$
We suppose that some dynamics gives rise to non-zero expectation values for $S$ and $F_S$. Here we won’t provide a complete microscopic model, which explains the origin of the parameters $F_S$ and $\langle S \rangle$ that will figure in our subsequent analysis; some constructions are described in the suggested reading. It is a good research problem to find a compelling model of the underlying dynamics. Instead, we will go ahead and immediately compute the superparticle spectrum for such a model. Ordinary squarks and sleptons gain mass through the two-loop diagrams shown in Fig. 14.2. While the prospect of computing a set of two-loop diagrams may seem intimidating, the computation is actually quite easy. If one treats $F_S/S$ as small, there is only one scale in the integrals. It is a straightforward matter to write down the diagrams, introduce Feynman parameters, and perform the calculation. There are also various non-trivial checks. For example, the sum of the diagrams must vanish in the supersymmetric limit.

One obtains the following expressions for the scalar masses:

$$\tilde{m}^2 = 2\Lambda^2 \left[ C_3 \left( \frac{\alpha_3}{4\pi} \right)^2 + C_2 \left( \frac{\alpha_2}{4\pi} \right)^2 + \frac{5}{3} \left( \frac{Y}{2} \right)^2 \left( \frac{\alpha_1}{4\pi} \right)^2 \right],$$

(14.15)

where $\Lambda = F_S/S$, and $C_3 = 4/3$ for color triplets and zero for singlets, $C_2 = 3/4$ for weak doublets and zero for singlets. For the gaugino masses one obtains:

$$m_{\lambda_i} = C_i \frac{\alpha_i}{4\pi} \Lambda.$$  

(14.16)

This expression is valid only to lowest order in $\Lambda$. Higher-order corrections have been computed; it is straightforward to compute exactly in $\Lambda$.

All of these masses are positive, and they are described in terms of a single new parameter, $\Lambda$. The lightest new particles are the partners of the $SU(3) \times SU(2)$ singlet leptons. If their masses are of order 100 GeV, we have that $\Lambda \sim 30$ TeV. The spectrum has a high degree of degeneracy. In this approximation, the masses
of the squarks and sleptons are functions only of their gauge quantum numbers, so flavor-changing processes are suppressed. Flavor violation arises only through Yukawa couplings, and these can appear only in graphs at high loop order. It is further suppressed because all but the top Yukawa coupling is small.

Apart from the parameter $\Lambda$, one has the $\mu$ and $B\mu$ parameters (both complex), for a total of five. This is three beyond the minimal Standard Model. If the underlying susy-breaking theory conserves CP, this can eliminate the phases, reducing the number of parameters by two.

**$SU(2) \times U(1)$ breaking**

At lowest order, all of the squark and slepton masses are positive. The large top quark Yukawa coupling leads to large corrections to $m^2_{H_u}$, however, which drive $SU(2) \times U(1)$ breaking. The calculation is just a repeat of one we have done in the case of the MSSM. Treating the mass of $\tilde{t}$ as independent of momentum is consistent, provided we cut the integral off at a scale of order $\Lambda$ (at this scale, the calculation leading to Eq. (14.15) breaks down, and the propagator falls rapidly with momentum) and we have

$$m^2_{H_u} = \left(m^2_{H_u}\right)_0 - \frac{6y_t^2}{16\pi^2} \ln \left(\frac{\Lambda^2}{m^2_{\tilde{t}}}\right) \left(m^2_{\tilde{t}}\right)_0.$$  (14.17)

While the loop correction is nominally a three-loop effect, because the stop mass arises from gluon loops while the Higgs mass arises at lowest order from $W$ loops, we have a substantial effect

$$\left(\frac{m^2_{\tilde{t}}}{m^2_{H_u}}\right)_0 = \frac{16}{9} \left(\frac{\alpha_3}{\alpha_2}\right)^2 \sim 20$$  (14.18)

and the Higgs mass-squared is negative. These contributions are quite large, and it is usually necessary to tune the $\mu$-term and other possible contributions to the Higgs mass to obtain sufficiently small $W$ and $Z$ masses.

**Light gravitino phenomenology**

There are other striking features of these models. One of the more interesting is that the lightest supersymmetric particle, or LSP, is the gravitino. Its mass is

$$m_{3/2} = 2.5 \left(\frac{F}{100 \text{ TeV}}\right)^2 \text{ eV}.$$  (14.19)

The next-to-lightest supersymmetric particle, or NLSP, can be a neutralino, or a charged right-handed slepton. The NLSP will decay to its superpartner plus a gravitino in a time long compared with typical microscopic times, but still quite short. The lifetime can be determined from low-energy theorems, in a manner reminiscent of the calculation of the pion lifetime. Just as the chiral currents are
linear in the (nearly massless) pion field,

\[ j^\mu_5 = f_\pi \partial^\mu \pi \quad \partial_\mu j^\mu_5 = \partial^2 \pi \approx 0, \]

so the supersymmetry current is linear in the goldstino, \( G \):

\[ j_\mu = F \gamma^\mu G + \sigma^{\mu\nu\lambda} F_{\mu\nu} + \cdots, \]

where \( F \), here, is the goldstino decay constant. From this, if one assumes that the LSP is mostly photino, one can calculate the amplitude for \( \tilde{\gamma} \rightarrow \gamma \) in much the same way one considers processes in current algebra. From Eq. (14.21), one sees that \( \partial_\mu j_\mu \) is an interpolating field for \( G \), so:

\[ \langle G \gamma | \tilde{\gamma} \rangle = \frac{1}{F} \langle \gamma | \partial_\mu j_\mu | \tilde{\gamma} \rangle. \]

The matrix element can be evaluated by examining the second term in the current, Eq. (14.21), and noting that \( \partial \chi = m_\chi \lambda \).

Given the matrix element, the calculation of the NLSP lifetime is straightforward, and yields

\[ \Gamma(\tilde{\gamma} \rightarrow G\gamma) = \frac{\cos^2 \theta_W m_{\tilde{\gamma}}^5}{16\pi F^2}. \]

This yields a decay length:

\[ c\tau = 130 \left( \frac{100 \text{ GeV}}{m_{\tilde{\gamma}}} \right)^5 \left( \frac{\sqrt{F}}{100 \text{ TeV}} \right)^4 \text{ } \mu\text{m}. \]

In other words, if \( F \) is not too large, the NLSP may decay in the detector. One even has the possibility of measurable displaced vertices. The signatures of such low decay constants would be quite spectacular. Assuming the photino (bino) is the NLSP, one has processes such as \( e^+ e^- \rightarrow \gamma \gamma + E_T \) and \( p\bar{b} \rightarrow e^+ e^- \gamma \gamma + E_T \), as indicated in Fig. 14.3, where \( E_T \) is the missing transverse energy.
Suggested reading

There are a number of good reviews of dynamical supersymmetry breaking, including those of Shadmi and Shirman (2000) and Terning (2003). The former includes catalogs of models and mechanisms. There is a large literature on gauge-mediated models and their phenomenology; a good review is provided by Giudice and Rattazzi (1999). A clear exposition of the origin of anomaly mediation is provided by Bagger et al. (2000) and in Weinberg’s text (1995).

Exercises

(1) Check that the $SU(N)$ models, with an antisymmetric tensor and $N - 4$ anti-fundamentals, have no flat directions, and that they have a non-anomalous $U(1)$ symmetry.

(2) Verify Eq. (14.13) using the Pauli–Villars procedure suggested in this chapter.
Theories with more than four conserved supercharges

In theories with more than four conserved supercharges (extended supersymmetry), the supersymmetry generators obey relations:

\[ \{ Q_I^\alpha, Q_J^\beta \} = \frac{1}{2} \delta^{IJ} \{ Q_I^\alpha, Q_J^\beta \} = Z^{IJ} \epsilon_{\alpha,\beta}. \]  

(15.1)

The quantities \( Z^{IJ} \) are known as central charges. We will see that these can arise in a number of physically interesting ways.

In theories with four supersymmetries, we have seen that supersymmetry provides powerful constraints on the possible dynamics. Theories with more than four supercharges (\( N > 1 \) in four dimensions) are not plausible as models of the real world, but they do have a number of remarkable features. As in some of our \( N = 1 \) examples, these theories typically have exact moduli spaces. Gauge theories with \( N = 4 \) supersymmetry exhibit an exact duality between electricity and magnetism. Theories with \( N = 2 \) supersymmetry have a rich – and tractable – dynamics, closely related to important problems in mathematics. In all of these cases, supersymmetry provides remarkable control over the dynamics, allowing one to address questions which are inaccessible in theories without supersymmetry. Supersymmetric theories in higher dimensions generally have more than four supersymmetries, and a number of the features of the theories we study in this chapter will reappear when we come to higher-dimensional field theories and string theory.

### 15.1 \( N = 2 \) theories: exact moduli spaces

Theories with \( N = 1 \) supersymmetry are tightly constrained, but theories with more supersymmetry are even more highly constrained. We have seen that often in perturbation theory \( N = 1 \) theories have moduli; non-perturbatively, sometimes, these moduli are lifted. In theories with \( N = 1 \) supersymmetry, detailed analysis is usually required to determine whether the moduli acquire potentials at the quantum level. For theories with more supersymmetries (\( N > 1 \) in four dimensions; \( N \geq 1 \))
in five or more dimensions), one can show rather easily that the moduli space is exact. Here we consider the case of $N = 2$ supersymmetry in four dimensions. These theories can also be described by a superspace, in this case built from two Grassmann spinors, $\theta$ and $\tilde{\theta}$. There are two basic types of superfields, called vector and hypermultiplets. The vectors are chiral with respect to both $D_\alpha$ and $\tilde{D}_\alpha$, and have an expansion, in the case of a $U(1)$ field:

$$\psi = \phi + \tilde{\theta}^\alpha W_\alpha + \tilde{\theta}^2 \tilde{D}^2 \phi^\dagger,$$

(15.2)

where $\phi$ is an $N = 1$ chiral multiplet and $W_\alpha$ is an $N = 1$ vector multiplet. The fact that $\phi^\dagger$ appears as the coefficient of the $\tilde{\theta}^2$ term is related to an additional constraint satisfied by $\psi$. This expression can be generalized to non-Abelian symmetries; the expression for the highest component of $\psi$ is then somewhat more complicated; we won’t need this here.

The theory possesses an $SU(2)$ $R$-symmetry under which $\theta$ and $\tilde{\theta}$ form a doublet. Under this symmetry, the scalar component of $\phi$, and the gauge field, are singlets, while $\psi$ and $\lambda$ form a doublet.

I won’t describe the hypermultiplets in detail, except to note that from the perspective of $N = 1$, they consist of two chiral multiplets. The two chiral multiplets transform as a doublet of the $SU(2)$. The superspace description of these multiplets is more complicated.

In the case of a non-Abelian theory, the vector field, $\psi^a$, is in the adjoint representation of the gauge group. For these fields, the Lagrangian has a very simple expression as an integral over half of the superspace:

$$\mathcal{L} = \int d^2\theta d^2\tilde{\theta} \, \psi^a \psi^a,$$

(15.3)

or, in terms of $N = 1$ components,

$$\mathcal{L} = \int d^2\theta \, W_\alpha^2 + \int d^4\theta \phi^\dagger e^V \phi.$$

(15.4)

The theory with vector fields alone has a classical moduli space, given by the values of the fields for which the scalar potential vanishes. Here this just means that the $D$ fields vanish. Written as a matrix,

$$D = [\phi, \phi^\dagger],$$

(15.5)

which vanishes for diagonal $\phi$, i.e. for

$$\phi = \frac{a}{2} \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}.$$
15.2 A still simpler theory: $N = 4$ Yang–Mills

For many physically interesting questions, one can focus on the effective theory for the light fields. In the present case, the light field is the vector multiplet, $\psi$. Roughly,

$$\psi \approx \psi^a \psi^a = a^2 + a \delta \psi^3 + \cdots .$$

What kind of effective action can we write for $\psi$? At the level of terms with up to four derivatives, the most general effective Lagrangian has the form:

$$L = \int d^2 \theta d^2 \tilde{\theta} f(\psi) + \int d^8 \theta \mathcal{H}(\psi, \psi^\dagger).$$

Terms with covariant derivatives correspond to terms with more than four derivatives, when written in terms of ordinary component fields.

The first striking result we can read off from this Lagrangian, with no knowledge of $\mathcal{H}$ and $f$, is that there is no potential for $\phi$, i.e. the moduli space is exact. This statement is true perturbatively and non-perturbatively.

One can next ask about the function $f$. This function determines the effective coupling in the low-energy theory, and is the object studied by Seiberg and Witten that we will discuss in Section 15.4.

15.2 A still simpler theory: $N = 4$ Yang–Mills

The $N = 4$ Yang–Mills theory is an interesting theory in its own right: it is finite and conformally invariant. It also plays an important role in our current understanding of non-perturbative aspects of string theory. The $N = 4$ Yang–Mills has 16 supercharges, and is even more tightly constrained than the $N = 2$ theories. First, we should describe the theory. In the language of $N = 2$ supersymmetry, it consists of one vector multiplet and one hypermultiplet. In terms of $N = 1$ superfields, it contains three chiral superfields, $\phi_i$, and a vector multiplet. The Lagrangian is

$$L = \int d^2 \theta W_\alpha^2 + \int d^4 \theta \phi_i^\dagger e^V \phi_i + \int d^2 \theta \phi_i^a \phi_j^b \phi_k^c \epsilon_{ijk} \epsilon^{abc}.$$  

In the above description, there is a manifest $SU(3) \times U(1)_R$ symmetry. Under this symmetry, the $\phi_i$s have $U(1)_R$ charge 2/3, and form a triplet of the $SU(3)$. But the real symmetry is larger – it is $SU(4)$. Under this symmetry, the four Weyl fermions form a 4, while the 6 scalars transform in the 6. Thinking of these theories as the low-energy limits of toroidal compactifications of the heterotic string will later give us a heuristic understanding of this $SU(4)$: it reflects the $O(6)$ symmetry of the compactified 6 dimensions. In string theory, this symmetry is broken by

---

1 This, and essentially all of the effective actions we will discuss, should be thought of as Wilsonian effective actions, obtained by integrating out heavy fields and high-momentum modes.
15 Theories with more than four conserved supercharges

the compactification manifold; this reflects itself in higher-derivative, symmetry-breaking operators.

In the $N = 4$ theory, there is, again, no modification of the moduli space, perturbatively or non-perturbatively. This can be understood in a variety of ways. We can use the $N = 2$ description of the theory, defining the vector multiplet to contain the $N = 1$ vector and one (arbitrarily chosen) chiral multiplet. Then an identical argument to that given above insures that there is no superpotential for the chiral multiplet alone. The $SU(3)$ symmetry then insures that there is no superpotential for any of the chiral multiplets. Indeed, we can make an argument directly in the language of $N = 1$ supersymmetry. If we try to construct a superpotential for the low energy theory in the flat directions, it must be an $SU(3)$-invariant, holomorphic function of the $\phi_i$s. But there is no such object.

Similarly, it is easy to see that there are no corrections to the gauge couplings. For example, in the $N = 2$ language, we want to ask what sort of function, $f$, is allowed in

$$L = \int d^2 \theta d^2 \bar{\theta} f(\psi).$$

But the theory has a $U(1)$ $R$-invariance under which

$$\psi \to e^{2i/3\alpha} \psi \quad \theta \to e^{i\alpha} \bar{\theta} \to e^{-i\alpha} \bar{\theta}.$$ (15.11)

Already, then,

$$\int d^2 \theta d^2 \bar{\theta} \psi \psi$$

(15.12)

is the unique structure which respects these symmetries. Now we can introduce a background dilaton field, $\tau$. Classically, the theory is invariant under shifts in the real part of $\tau$, $\tau \to \tau + \beta$. This insures that there are no perturbative corrections to the gauge couplings. More work is required to show that there are no non-perturbative corrections either.

One can also show that the quantity $\mathcal{H}$ in Eq. (15.8) is unique in this theory, again using the symmetries. The expression:

$$\mathcal{H} = c \ln(\psi) \ln(\psi^\dagger),$$

(15.13)

respects all of the symmetries. At first sight, it might appear to violate scale invariance; given that $\psi$ is dimensionful, one would expect a scale, $\Lambda$, sitting in the logarithm. However, it is easy to see that if one integrates over the full superspace, any $\Lambda$-dependence disappears, since $\psi$ is chiral. Similarly, if one considers the $U(1)$ $R$-transformation, the shift in the Lagrangian vanishes after the integration over superspace. To see that this expression is not renormalized, one merely needs to note that any non-trivial $\tau$-dependence spoils these two properties. As a result, in
the case of $SU(2)$, the four derivative terms in the Lagrangian are not renormalized. Note that this argument is non-perturbative. It can be generalized to an even larger class of higher-dimension operators.

### 15.3 A deeper understanding of the BPS condition

In our study of monopoles, we saw that under certain circumstances, the complicated second-order non-linear differential equations reduced to first-order differential equations. The main condition is that the potential should vanish. We are now quite used to the idea that supersymmetric theories often have moduli, and have seen that this is an exact feature of $N = 4$ and many $N = 2$ theories. In the case of an $N = 2$ supersymmetric gauge theory, the potential is just that arising from the $D$-term, and one can construct a Prasad–Sommerfield solution. We will now see that the BPS condition is not simply magic, but is a consequence of the extended supersymmetry of the theory. The resulting mass formula, as a consequence, is exact; it is not simply a feature of the classical theory, but a property of the full quantum theory. This sort of BPS condition is relevant not only to the study of magnetic monopoles but to topological objects in various dimensions and contexts, particularly in string theory. Here we will give the flavor of the argument, without worrying carefully about factors of two. More details are worked out in the Exercises and the References.

First, we show that the electric and magnetic charges enter in the supersymmetry algebra of this theory as central charges. Thinking of this as an $N = 1$ theory, we have seen that the supercurrents take the form:

\begin{equation}
S^\mu_a = \sigma^\mu_{\alpha \dot{\beta}} (\sigma^{\rho \sigma})^{\dot{\beta} \dot{\gamma}} F_{\rho \sigma} \lambda_{\dot{\gamma}} + \partial_\rho \phi^i \sigma^\rho_{\alpha \dot{\beta}} (\sigma^\mu)^{\dot{\beta} \dot{\gamma}} \psi^{i \dot{\gamma}} + \text{F-term pieces.} \tag{15.14}
\end{equation}

In this theory, however, there is an $SU(4)$ symmetry, and the supercurrents should transform as a 4. It is not hard to guess the others, even without writing down the transformation laws of the fields:

\begin{equation}
S^l_{\mu \alpha} = \sigma^\mu_{\alpha \dot{\beta}} (\sigma^{\rho \sigma})^{\dot{\beta} \dot{\gamma}} F_{\rho \sigma} \psi_i^{\dot{\gamma}} + \epsilon_{ijk} \partial_\rho \phi^j \sigma^\rho_{\alpha \dot{\beta}} (\sigma^\mu)^{\dot{\beta} \dot{\gamma}} \psi^{k \dot{\gamma}} + \text{F-term pieces.} \tag{15.15}
\end{equation}

We are interested in proving bounds on the mass. It is useful to define Hermitian combinations of the $Q$s, since we want to study positivity constraints. In this case, it is more convenient to write a four-component expression, using a Majorana (real) basis for the $\gamma$ matrices. Taking an $N = 2$ subgroup, and carefully computing the commutators of the charges:

\begin{equation}
\{ Q_{\alpha i}, Q_{\beta j} \} = \delta_{ij} \gamma^\mu_{\alpha \beta} P_\mu + \epsilon_{ij} (\delta_{\alpha \beta} U_k + (\gamma_5)_{\alpha \beta} V_k). \tag{15.16}
\end{equation}
Here

\[ U_k = \int d^3 \hat{x} \hat{\partial}_i (\phi_{re_i}^a E_i^a + \phi_{im_i}^a B_i^a) \]
\[ V_k = \int d^3 \hat{x} \hat{\partial}_i (\phi_{im_i}^a E_i^a + \phi_{re_i}^a B_i^a). \]  \hspace{1cm} (15.17)

In the Higgs phase, the integrals are, by Gauss’s theorem, electric and magnetic charges, multiplied by the Higgs expectation value.

From these relations, we can derive bounds on masses, using the fact that \( Q^2 \) is a positive operator. Taking the expectation of both sides, we have, for an electrically neutral system of mass \( M \) in its rest frame,

\[ M \pm Q_m v \geq 0. \]  \hspace{1cm} (15.18)

This bound is saturated when \( Q \) annihilates the state. Examining the form of \( Q_\alpha \), this is just the BPS condition.

### 15.3.1 \( N = 4 \) Yang–Mills theories and electric–magnetic duality

This is a theory which, from the point of view of \( N = 1 \) supersymmetry, contains a gauge multiplet and three chiral multiplets in the adjoint representation. In addition to the interactions implied by the gauge symmetry, there is a superpotential:

\[ W = \frac{1}{6} f_{abc} \epsilon_{ijk} \Phi_i^a \Phi_j^b \Phi_k^c. \]  \hspace{1cm} (15.19)

We have normalized the kinetic terms for the fields \( \Phi \) with a \( 1/g^2 \) out front. So this interaction has strength related to the strength of the gauge interactions. This theory has a global \( SU(4) \) symmetry. Under this symmetry, the 4 adjoint fermions transform as a 4; the scalars transform as a 6, and the gauge bosons are invariant. The theory has a large set of flat directions. If we simply take all of the \( \Phi \) fields as matrices, to be diagonal the potential vanishes. As a result, this theory has monopoles of the BPS type.

This theory has a symmetry even larger than the \( Z_2 \) duality symmetry we contemplated when we examined Maxwell’s equations; the full symmetry is \( SL(2, Z) \). We might guess this, first, by remembering that the coupling constant is part of the holomorphic variable:

\[ \tau = \frac{\theta}{2\pi} + \frac{4\pi i}{e^2}. \]  \hspace{1cm} (15.20)

So in addition to our conjectured \( e \to 1/e \) symmetry, there is a symmetry \( \theta \to \)
$\theta + 2\pi$. So in terms of $\tau$, we have the two symmetry transformations,

$$\tau \rightarrow -\frac{1}{\tau}, \quad \tau \rightarrow \tau + 1.$$  

(15.21)

Together, these transformations generate the group $SL(2, \mathbb{Z})$:

$$\tau \rightarrow \frac{a\tau + b}{c\tau + d} \quad ad - bc = 1.$$  

(15.22)

Now we can look at our BPS formula. To understand whether it respects the $SL(2, \mathbb{Z})$ symmetry we need to understand how this symmetry acts on the states. Writing

$$M = e Q_e v + \frac{Q_m v}{e}$$

with

$$Q_e = n_e - n_m \frac{\theta}{2\pi}, \quad Q_m = 4\pi \frac{n_m}{e}$$  

(15.24)

the spectrum is invariant under the $SL(2, \mathbb{Z})$ transformation of $\tau$, accompanied by:

$$\begin{pmatrix} n_e \\ n_m \end{pmatrix} \rightarrow \begin{pmatrix} d & -b \\ c & -d \end{pmatrix} \begin{pmatrix} n_e \\ n_m \end{pmatrix}.$$  

(15.25)

Because it follows from the underlying supersymmetry, the mass formula is exact, so this duality of the spectrum of BPS objects is a non-perturbative statement about the theory.

### 15.4 Seiberg–Witten theory

We have seen that $N = 4$ theories are remarkably constrained, and this allowed us, for example, to explore an exact duality between electricity and magnetism. Still, these theories are not nearly as rich as field theories with $N \leq 1$ supersymmetry. The $N = 2$ theories are still quite constrained, but exhibit a much more interesting array of phenomena. They illustrate the power provided by supersymmetry over non-perturbative dynamics. They will also allow us to study phenomena associated with magnetic monopoles in a quite non-trivial way. In this section, we will provide a brief introduction to the subject known as Seiberg–Witten theory. This subject has applications not only in quantum field theory, but also for our understanding of string theory and, perhaps most dramatically, in mathematics.

It is convenient to describe the $N = 2$ theories in $N = 1$ language. The basic $N = 2$ multiplets are the vector multiplet and the tensor (or hyper) multiplet. From the point of view of $N = 1$ supersymmetry, the vector contains a vector multiplet.
and a chiral multiplet. The tensor contains two chiral fields. We will focus mainly on theories with only vector multiplets, with gauge group $SU(2)$. In the $N = 1$ description, the fields are a vector multiplet, $V$, and a chiral multiplet, $\phi$, both in the adjoint representation. The Lagrangian density is:

$$
\mathcal{L} = \int d^4 \theta \frac{1}{g^2} \phi^\dagger V \phi - \frac{i}{16 \pi} \int d^2 \theta \tau W^{a \alpha} W^a_{\alpha} + \text{h.c.}
$$

(15.26)

Here

$$
\tau = \frac{\theta}{2\pi} + i4\pi g^{-2}.
$$

(15.27)

The $1/g^2$ in front of the chiral field kinetic term is somewhat unconventional, but it makes the $N = 2$ supersymmetry more obvious. As we indicated earlier, one way to understand the $N = 2$ supersymmetry is to note that the Lagrangian we have written has a global $SU(2)$ symmetry. Under the symmetry, the scalar fields, $\phi^a$, and the gauge fields $A^a_\mu$ are singlets, while the gauginos, $\lambda^a$, and the fermionic components of $\phi$, $\psi^a$, transform as a doublet. Acting on the conventional $N = 1$ generators, the $SU(2)$ produces four new generators. So we have generators $Q^A_\alpha$, with $A = 1, 2$.

As it stands, the model has flat directions, with

$$
\phi = \frac{a}{2} \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}.
$$

(15.28)

In these directions, the spectrum consists of two massive and one massless gauge bosons, a massive complex scalar, degenerate with the gauge bosons, and a massive Dirac fermion, as well as a massless vector and a massless chiral multiplet. The masses of all of these particles are

$$
M_W = \sqrt{2}a.
$$

(15.29)

This is precisely the right number of states to fill an $N = 2$ multiplet. Actually, this multiplet is a BPS multiplet. It is annihilated by half of the supersymmetry generators. The classical theory possesses, in addition to the global $SU(2)$ symmetry, an anomalous $U(1)$ symmetry:

$$
\phi \to e^{i\alpha \phi} \quad \psi \to e^{i\alpha} \psi.
$$

(15.30)

Under this symmetry,

$$
\theta \to \theta - 4\alpha
$$

(15.31)

or

$$
\tau \to \tau - 2\pi \alpha.
$$

(15.32)
Because physics is periodic in $\theta$ with period $2\pi$, $\alpha = \pi/2$ is a symmetry, i.e. the theory has a $Z_4$ symmetry:

$$\phi \rightarrow e^{i\pi/2} \phi.$$  \hfill (15.33)

Note that $\phi$ is not gauge-invariant. A suitable gauge-invariant variable for the analysis of this theory is:

$$u = \langle \text{Tr} \phi^3 \rangle.$$  \hfill (15.34)

Under the discrete symmetry, $u \rightarrow -u$; at weak coupling,

$$u \approx a^2.$$  \hfill (15.35)

The spectrum of this theory includes magnetic monopoles, in general with electric charges. At the classical level, the monopole solutions in this theory are precisely those of Prasad and Sommerfield, with mass

$$M_M = 4\pi \sqrt{2} \frac{a}{g^2}.$$  \hfill (15.36)

As in the $N = 4$ theory, there is a BPS formula for the masses:

$$m = \sqrt{2}|aQ_e + a_DQ_M|.$$  \hfill (15.37)

At tree level,

$$a_D = \frac{4\pi}{g^2} ia = \tau a,$$  \hfill (15.38)

where the last equation holds if $\theta = 0$. The $i$ in this formula is not immediately obvious. To see that it must be present, consider the case of dyonic excitations of monopoles. These should have energy of order the charge, with no factors of $1/g^2$. This is insured by the relative phase between $a$ and $a_D$. These formulas will receive corrections in perturbation theory and beyond; our goal is to understand the form of these corrections and their (dramatic) physical implications.

Equation (15.38) is not even meaningful as it stands; $\tau$ is a function of scale. Instead, Seiberg and Witten suggested that

$$\tau = \frac{d a_D}{d a}.$$  \hfill (15.39)

They also proposed the existence of a duality symmetry, under which

$$a_D \leftrightarrow a \quad \tau \rightarrow -\frac{1}{\tau}.$$  \hfill (15.40)

To formulate our questions more precisely, and to investigate this proposal, it is helpful, as always, to consider a low-energy effective action. This action should respect the $N = 2$ supersymmetry; in $N = 1$ language, this means that the Lagrangian
Theories with more than four conserved supercharges should take the form:

\[ \mathcal{L} = \int d^4 \theta K(a, \bar{a}) - \frac{i}{16\pi^2} \int d^2 \theta \tau(a) W^a W_a. \]  

(15.41)

The \( N = 2 \) supersymmetry implies a relation between \( K \) and \( \tau \); without it, these would be independent quantities. Both quantities can be obtained from a holomorphic function called the prepotential, \( \mathcal{F}(a) \):

\[ \tau = \frac{d^2 \mathcal{F}}{da^2}, \quad K = \frac{1}{4\pi} \frac{d \mathcal{F}}{da} a^*. \]  

(15.42)

From

\[ \tau = \frac{da_D}{da} = \frac{d}{da} \left( \frac{d \mathcal{F}}{da} \right) \]  

(15.43)

we have

\[ \frac{d \mathcal{F}}{da} = ia_D, \]  

(15.44)

so

\[ K = \frac{1}{4\pi} \text{Im} a_D a^*. \]  

(15.45)

Our goal will be to obtain a non-perturbative description of \( \mathcal{F} \). At weak coupling, the beta function of this theory is obtained from \( b_0 = 3N - N = 2N = 4 \), so

\[ \tau = \frac{i}{\pi} \ln(u/\Lambda^2). \]  

(15.46)

As a check on this formula, note that, under \( u \to e^{2i\alpha} u, \theta \to \theta - 4\alpha \), so

\[ \tau = \frac{\theta}{2\pi} + 4\pi i g^{-2} \to \tau - \frac{2i\alpha}{\pi} \]  

(15.47)

and this is precisely the behavior of the formula (Eq. (15.46)).

This is similar to phenomena we have seen in \( N = 1 \) theories. But when we consider the monopoles of the theory, the situation becomes more interesting. First, note that, using the leading order result for \( \tau \),

\[ a_D = \frac{2i}{\pi} \left( a \ln \left( \frac{a}{\Lambda} \right) - a \right). \]  

(15.48)

So, under the transformation of \( u, u \to e^{i\alpha} u \),

\[ a_D \to e^{i\alpha/4} \left( a_D - \frac{\alpha}{2\pi} a \right). \]  

(15.49)

Our BPS mass formula transforms to:

\[ m \to \sqrt{2} \left| a \left( Q_e - \frac{4\alpha}{2\pi} Q_m \right) + a_D Q_m \right|. \]  

(15.50)
This is the Witten effect, which we have discussed earlier: in the presence of $\theta$, a magnetic monopole acquires an electric charge. More generally, the spectrum of dyons is altered.

Consider now what happens when we do a full $2\pi$ change of $\theta$ ($u \rightarrow -u$). This should be a symmetry. This is true in this case, but in a subtle way: the spectrum of the dyonic excitations of the theory is unchanged, but the charges of the dyons have shifted by one fundamental unit. This, in turn, is related to the branched structure of $\tau$.

At the non-perturbative level, the structure is even richer. We might expect

$$\tau(u) = \frac{i}{\pi} \ln(u/\Lambda^2) + \alpha e^{-\frac{8\pi^2}{g^2}} + \beta e^{-\frac{8\pi^2}{g^2}} + \cdots.$$  

(15.51)

Note that, interpreting $\exp(-8\pi^2/g^2)$ as $\exp(2\pi i \tau)$, each term in this series has the correct periodicity in $\theta$. Moreover,

$$\exp(2\pi i \tau) = \frac{\Lambda^2}{u^2}.$$  

(15.52)

These corrections have precisely the correct structure to be instanton corrections, and these instanton corrections have been computed. But we can, following Seiberg and Witten, be bolder and consider what happens when $g$ becomes large. Naively, we might expect that some monopoles become light. Associated with this, $\tau$ may have a singularity at some point, $u_0 = \gamma/\Lambda^2$, where $\Lambda$ is the renormalization group invariant mass of the theory. In light of the $Z_2$ symmetry, there must also be a singularity at $-u_0$. Such a singularity arises because a particle is becoming massless. If we think of $\tau_D$ as the dual of $\tau$, then there is an electrically charged light field of unit charge; more precisely, there must be two particles of opposite charge, in order that they can gain mass. So $\tau_D$ has the structure:

$$\tau_D = -\frac{2i}{2\pi} \ln(m_M).$$  

(15.53)

Assuming that $a_D$ has a simple zero,

$$a_D \approx b(u - u_0); \quad m_M = \sqrt{2}a_D.$$  

(15.54)

then

$$\tau_D = -\frac{i}{\pi} \ln(u - u_0) = -\frac{1}{\tau(u)}.$$  

(15.55)

Starting with the relation

$$\frac{da}{da_D} = -\tau_D = -\frac{i}{\pi} \ln(a_D)$$  

(15.56)
we have
\[ a = \frac{i}{\pi} (a_D \ln a_D - a_D). \] (15.57)

Similarly, we can consider the behavior at the point \(-u_0\). This is the mirror of the previous case, but we must be careful about the relation of \(a, a_D\). These are connected by the symmetry transformation:
\[ \tilde{a} = ia, \quad \tilde{a}_D = i(a_D - a). \] (15.58)

Now:
\[ \tau_D = -\frac{1}{\tau(u)} = -\frac{i}{\pi} \ln(u + u_0) \] (15.59)

and
\[ \tilde{\alpha} = \frac{1}{\pi} (\tilde{a}_D \ln \tilde{a}_D - \tilde{a}_D). \] (15.60)

Going around the singularities, at \(u_0\),
\[ a \to a - 2a_D; \quad a_D \to a_D, \] (15.61)

while at \(-u_0\),
\[ a \to 3a - 2a_D; \quad a_D \to 2a - a_D. \] (15.62)

This should be compared with the effect of going around \(2\pi\) at large \(u\): \(a \to -a; \quad a_D \to -(a_D - a)\). Assuming that these are the only singularities, we can, from this information, reconstruct \(\tau\). We won’t give the full solution of Seiberg and Witten here, but the basic idea is to note that \(\tau(u)\) is the modular parameter of a two-dimensional torus and to reconstruct the torus.

This analysis has allowed us to study the theory deep in the non-perturbative region. Seiberg and Witten uncovered a non-trivial duality, a limit in which monopoles become massless, and provided insight into confinement. These sorts of ideas have been extended to other theories, to theories in higher dimensions, and have provided insight into many phenomena in string theory, quantum gravity and pure mathematics.

**Suggested reading**

The lectures by Lykken (1996) provide a brief introduction to aspects of \(N > 1\) supersymmetry. Olive and Witten (1978) first clarified the connection of the BPS condition and extended supersymmetry, in a short and quite readable paper. Harvey (1996) provides a more extensive introduction to monopoles and the BPS condition.
The original papers of Seiberg and Witten (1994) are quite clear; Peskin’s lectures, which we have borrowed from extensively here, provide a brief and very clear introduction to the subject.

**Exercises**

(1) Check the supersymmetry commutators in extended supersymmetry (Eq. (15.16)).
(2) Rewrite the supersymmetry commutators in a real basis for the Dirac matrices. Using this, verify the BPS inequality.
(3) Check that the monopole/dyon spectrum in Eq. (15.23) is invariant under $SL(2, \mathbb{Z})$ transformations.
While motivated in part by the hopes of building phenomenologically successful models of particle physics, we have uncovered in our study of supersymmetric theories a rich trove of field theory phenomena. Supersymmetry provides powerful constraints on dynamics. In this chapter, we will discover more remarkable features of supersymmetric field theories. We will first study classes of (super)conformally invariant field theories. Then we will turn to the dynamics of supersymmetric QCD with $N_f \geq N_c$, where we will encounter new, and rather unfamiliar, types of behavior.

16.1 Conformally invariant field theories

In quantum field theory, theories which are classically scale-invariant typically are not scale invariant at the quantum level. QCD is a familiar example. In the absence of quark masses, we believe the theory confines and has a mass gap. The CP$^N$ models are an example where we were able to show systematically how a mass gap can arise in a scale-invariant theory. The breaking of scale invariance in all of these cases is associated with the need to impose a cutoff on the high-energy behavior of the theory. In a more Wilsonian language, one needs to specify a scale where the theory is defined, and this requirement breaks the scale invariance.

There is, however, a subset of field theories which are scale invariant. We have seen this in the case of $N = 4$ supersymmetric field theories in four dimensions. In this section, we will see that this phenomenon can occur in $N = 1$ theories, and explore some of its consequences. In the next section we will discuss a set of dualities among $N = 1$ supersymmetric field theories, in which conformal invariance plays a crucial role.

In order that a theory exhibit conformal invariance, it is necessary that its beta ($\beta$-)function vanish. At first sight, it would seem difficult to use perturbation theory to find such theories. For example, one might try to choose the number of flavors
and colors so that the one-loop beta function vanishes. But then the two-loop beta function will generally not vanish. One could try to balance the first term against the second, but this would generally require $g^4 \sim g^2$, and there would not be a good perturbation expansion. Banks and Zaks pointed out that one can find such theories by adopting a different strategy. By taking the number of flavors and colors large, one can arrange that the coefficient of the one-loop beta function almost vanishes, and choose the coupling so that it cancels the two-loop beta function. In this situation, one can arrange a cancellation perturbatively, order by order. The small parameter is $1/N$, where $N$ is the number of colors.

We can illustrate this idea in the framework of supersymmetric theories with $N$ colors and $N_f$ flavors. The beta function, through two loops, is given by

$$
\beta(g) = -\frac{g^3}{16\pi^2}b_0 - \frac{g^5}{(16\pi^2)^2}b_1
$$

(16.1)

where

$$
b_0 = 3N - N_f \quad b_1 = 6N^2 - 2NN_F + 4N_F \frac{(N^2 - 1)}{2N}.
$$

(16.2)

In the limit of very large $N$, $N_f$, we write: $N_f = 3N - \epsilon$, where $\epsilon$ is an integer of order one. Then, to leading order in $1/N$, the beta function vanishes for a particular coupling, $g_0$:

$$
\frac{g_0^2}{16\pi^2} = \frac{\epsilon}{6N^2}.
$$

(16.3)

Perturbative diagrams behave as $(g^2 N)^n$, and $g^2 N$ is small. So at each order, one can make small adjustments in $g^2$ so as to make the beta function vanish.

A theory in which the beta function vanishes is genuinely conformally invariant. We will not give a detailed discussion of the conformal group here; the exercises at the end of this chapter guide the reader through some of the features of the conformal group; good reviews are described in the suggested reading. Here we will just mention a few general features, and then perform some computations at our Banks–Zaks fixed point theories to verify these.

Without supersymmetry, the generators of the conformal group include the Lorentz generators and the translations:

$$
M_{\mu \nu} = -i(x_\mu \partial_\nu - x_\nu \partial_\mu) \quad P_\mu = -i \partial_\mu
$$

(16.4)

and the generators of “special conformal transformations” and dilatations:

$$
K_\mu = -i(x^2 \partial_\mu - 2x_\mu x_\alpha \partial^\alpha) \quad D = ix_\alpha \partial^\alpha.
$$

(16.5)

In the presence of supersymmetry, the group is enlarged. In addition to the bosonic generators above and the supersymmetry generators, there are a group
of superconformal generators, of the form

\[ S_\alpha = X_\mu \sigma_{\alpha\dot{\alpha}}^{\mu} Q^{\dot{\alpha}}. \] (16.6)

We encountered these in our analysis of the zero modes of the Yang–Mills instanton. The superconformal algebra also includes an R-symmetry current.

Conformal invariance implies the vanishing of \( T_\mu \). In the superconformal case, the superconformal generators and the divergence of the \( R \) current also vanish. One can prove a relation between the dimension and the \( R \) charge:

\[ d \geq \frac{3}{2} |R|. \] (16.7)

States for which the inequality is satisfied are known as chiral primaries. An interesting case is provided by the fixed point theories we have introduced above. For these, the charge of the chiral fields, \( Q \) and \( \bar{Q} \), under the non-anomalous symmetry is

\[ R_{Q, \bar{Q}} = \frac{N_f - N}{N_f}. \] (16.8)

Assuming that these fields are chiral primaries, it follows that their dimension satisfies:

\[ d - 1 = -\frac{3N - N_f}{2N_f} = -\frac{\epsilon}{6N}. \] (16.9)

At weak coupling, on the other hand, the anomalous dimensions of these fields are known:

\[ \gamma = -\frac{g^2}{16\pi^2} N = -\frac{\epsilon}{6N}. \] (16.10)

In this chapter, we will see that supersymmetric QCD, for a range of \( N_f \) and \( N \), exhibits conformal fixed points for which the coupling is not small.

### 16.2 More supersymmetric QCD

We have studied the dynamics of supersymmetric QCD with \( N_f < N \), and observed a range of phenomena: non-perturbative effects which lift the degeneracy among different vacua and non-perturbative supersymmetry breaking. In the cases \( N_f \geq N_c \), there are exact moduli, even non-perturbatively. For phenomenology, such theories are probably of no relevance, but Seiberg realized that from a theoretical point of view, these theories are a bonanza. The existence of moduli implies a great deal of control over the dynamics. One can understand much about the strongly coupled regimes of these theories, allowing insights into non-perturbative dynamics unavailable in theories without supersymmetry. We will be able to answer questions...
such as: are there unbroken global symmetries in some region of the moduli space? In regions of strong coupling, are there massless composite particles?

16.3 $N_f = N_c$

The case $N_f = N_c$ already raises issues beyond those of $N_f < N_c$. First, we have seen that there is no invariant superpotential one can write. As a result, there is an exact moduli space, perturbatively and non-perturbatively. But there is still an interesting quantum modification of the theory, first discussed by Seiberg.

Consider, first, the classical moduli space. Now, in addition to the vacua with $Q = \bar{Q}$ (up to flavor transformations) which we found previously, we can also have

$$Q = vl \quad \bar{Q} = 0 \quad \text{or} \quad Q \leftrightarrow \bar{Q}. \quad (16.11)$$

This is referred to as the “baryonic branch,” since now the operator:

$$B = \epsilon_{i_1 \ldots i_N} \epsilon^{j_1 \ldots j_N} Q_{i_1}^{j_1} \cdots Q_{i_N}^{j_N} \quad (16.12)$$

is non-vanishing (or the corresponding “anti-baryon”).

Classically, these two classes of possibilities can be summarized in the condition:

$$\text{Det}(\bar{Q} Q) = \bar{B} B. \quad (16.13)$$

Now this condition is subject to quantum modifications. Both sides are completely neutral under the various flavor symmetries; in principle any function of $B \bar{B}$ or the determinant would be permitted as a modification. But we can use anomalous symmetries (with the anomalies canceled by shifts in $S$) to constrain any possible corrections. Consider, in particular, possible instanton corrections. These are proportional to

$$v^{2N} e^{-\frac{8\pi^2}{g^2}} \sim \Lambda^{2N} \quad (16.14)$$

and transform just like the left-hand side under the anomalous $R$-symmetry for which:

$$Q \rightarrow e^{i\alpha Q}. \quad (16.15)$$

So at the quantum level, the moduli space satisfies the condition:

$$\text{Det}(\bar{Q} Q) - \bar{B} B = c \Lambda^{2N}. \quad (16.16)$$

This is of just the right form to be generated by a 1-instanton correction. We will not do the calculation here which shows that the right-hand side is generated. But we can outline the main features. There are now 2 superconformal zero modes, 2 supersymmetry zero modes, $4N - 4$ zero modes associated with the
gluinos in the \((2, N - 2)\) representation of the \(SU(2) \times SU(N - 2)\) subgroup of \(SU(N)\) distinguished by the instanton, and \(2N\) matter zero modes. We want to compute the expectation value of an operator involving \(N\) scalars. To obtain a non-vanishing result, it is necessary to replace some of these fields with their classical values. Others must be contracted with Yukawa terms. The scalar field propagators in the instanton background are known, and the full calculation reasonably straightforward. Because the classical condition which defines the moduli space is modified, the moduli space of the \(N_f = N_c\) theory is referred to as the “quantum moduli space.” This phenomenon appears for other choices of gauge group as well.

### 16.3.1 Supersymmetry breaking in quantum moduli spaces

We have mentioned that in the \(3-2\) model, in the limit that the \(SU(2)\) gauge group is the strong group, supersymmetry breaking can be understood as resulting from an expectation value for \(QL\). The \(QL\) vev is non-zero since \(N = N_f = 2\). A larger class of models in which a quantum moduli space is responsible for dynamical supersymmetry is due to Intriligator and Thomas.

Consider a model with gauge group \(SU(2)\) and four doublets, \(Q_I, I = 1 \ldots 4\) (two “flavors”). Classically, this model has a moduli space labelled by the expectation values of the fields \(M_{IJ} = Q_I Q_J\). These satisfy \(\text{Pf}(M_{IJ}) = 0\), but, as have just seen, the quantum moduli space is different, and satisfies:

\[
\text{Pf}(\langle M_{IJ} \rangle) = \Lambda^4.
\]

(16.17)

Now add a set of singlets to the model, \(S_{IJ}\), with superpotential couplings

\[
W = \lambda_{IJ} S_{IJ} Q_I Q_J.
\]

(16.18)

Unbroken supersymmetry now requires

\[
\frac{\partial W}{\partial S_{IJ}} = Q_I Q_J = 0.
\]

(16.19)

However, this is incompatible with the quantum constraint. So supersymmetry is broken.

On the other hand, the model, classically, has flat directions in which \(S_{IJ} = s_{IJ}\), and all of the other fields vanish. So one might worry that there is runaway behavior in these directions, similar to that we saw in supersymmetric QCD. However, for large \(s\), it turns out that the energy grows at infinity. This can be established as

\[\text{1 In this expression, Pf denotes Pfaffian. The Pfaffian is defined for } 2N \times 2N \text{ antisymmetric matrices; it is essentially the square root of the determinant of the matrix.}\]
follows. Suppose all of the components of $S$ are large, $S \sim s \gg \Lambda_2$. In this limit, the low-energy theory is a pure $SU(2)$ gauge theory. In this theory, gluinos condense,

$$\langle \lambda \lambda \rangle = \Lambda_{LE}^3 = \lambda s \Lambda_2^2. \quad (16.20)$$

Here, $\Lambda_{LE}$ is the $\Lambda$ parameter of the low-energy theory.

At this level, then, the superpotential of the model behaves as

$$W_{\text{eff}} \sim \lambda S \Lambda_2^3. \quad (16.21)$$

and the potential is a constant,

$$V = |\Lambda_2|^4 |\lambda|^2. \quad (16.22)$$

The natural scale for the coupling, $\lambda$, which appears here is $\lambda(s)$. This is the correct answer in this case, and implies that for large $s$ the potential grows, since $\lambda$ is not asymptotically free. So the potential has a minimum, in a region of small $s$.

### 16.3.2 $N_f = N_c + 1$

For $N_f > N_c$, the classical moduli space is exact. But Seiberg has, again, pointed out a rich set of phenomena and given a classification of the different theories. As in the case of $N_f < N_c$, different phenomena occur for different values of $N_f$.

First, we need to introduce a new tool: the ’t Hooft anomaly matching conditions. ’t Hooft was motivated by the following question. When one looks at the repetitive structure of the quark and lepton generations, it is natural to wonder if the quarks and leptons themselves are bound states of some simpler constituents. ’t Hooft pointed out that if this idea is correct, the masses of the quarks and leptons are far smaller than the scale of the underlying interactions; even at that time, it was known that if these particles have any structure, it is on scales shorter than $100 \text{ GeV}^{-1}$.

’t Hooft argued that this could only be understood if the underlying interactions left an unbroken chiral symmetry.

One could go on and simply postulate that the symmetry is unbroken, but ’t Hooft realized that there are strong – and simple – constraints on such a possibility. Assuming that the underlying interactions are some strongly interacting non-Abelian gauge theory, ’t Hooft imagined gauging the global symmetries of the theory. In general, the resulting theory would be anomalous, but one could always cancel the anomalies by adding some “spectator” fields, fields transforming under the gauged flavor symmetries but not the underlying strong interactions. Below the confinement scale of the strong interactions, the flavor symmetries might be spontaneously broken, giving rise to Goldstone bosons, or there might be massless fermions. In either case, the low-energy theory must be anomaly-free, so the anomalies of either the Goldstone bosons or the massless fermions must be the same as in the
original theory. ’t Hooft added another condition, which he called the “decoupling” condition: he asked what happened if one added mass terms for some of the constituent fermions. He went on to show that these conditions are quite powerful, and that it is difficult to obtain a theory with unbroken chiral symmetries.

As we will see, Seiberg conjectured various patterns of unbroken symmetries for SUSY QCD. For these the ’t Hooft anomaly conditions provide a strong self-consistency check. In the case $N_f = N_c$, there is no point in the moduli space where the chiral symmetries are all unbroken. So let’s move on to the case $N_f = N_c + 1$. The global symmetry of the model is:

$$SU(N_f)_L \times SU(N_f)_R \times U(1)_B \times U(1)_R$$

where under $U(1)_R$, the quarks and antiquarks transform as:

$$Q_f, \bar{Q}_f \rightarrow e^{\frac{i\alpha}{N+1}} Q_f, \bar{Q}_f.$$  \hspace{1cm} (16.24)

In this theory, there are two various sorts of gauge invariant objects: the mesons, $M_{f,f} = \bar{Q}_f Q_f$ and the baryons, $B_f = \epsilon_{\alpha_1 \cdots \alpha_N} Q_{\alpha_1}^{i_1} Q_{\alpha_2}^{i_2} \cdots Q_{\alpha_N}^{i_N}$.

From these, we can build a superpotential invariant under all of the symmetries:

$$W = (\det M - B_{f,f} M_{f,f} B_f) \frac{1}{\Lambda^{b_0}}.$$  \hspace{1cm} (16.25)

As in all of our earlier cases, the power of $\Lambda$ is determined by dimensional arguments, but can also be verified by demanding holomorphy in the gauge coupling.

This superpotential has several interesting features. First, it has flat directions, as we would expect, corresponding to the flat directions of the underlying theory. But also, for the first time, there is a vacuum at the point where all of the fields vanish, $B = \bar{B} = M = 0$. At this point, all of the symmetries are unbroken. The ’t Hooft anomaly conditions provide an important consistency check on this whole picture. There are several anomalies to check ($SU(N_f)^3_L$, $SU(N_f)_R^3$, $SU(N_f)_L^2 U(1)_R$, $Tr U(1)_R$, $U(1)^2_B U(1)_R$, $U(1)^3_R$, etc.). The cancellations are quite non-trivial. In the exercises, the reader will have the opportunity to check these.

Another test comes from considering decoupling. If we add a mass for one set of fields, the theory should reduce to the $N_f = N$ case. As in examples with smaller numbers of fields, we take advantage of holomorphy, writing expressions for small values of the mass and continuing to large values. So we add to the superpotential a term:

$$m \bar{Q}_{N+1} Q_{N+1} = m M_{N+1,N+1}.$$  \hspace{1cm} (16.26)

We want to integrate out the massive fields. Because of the global symmetry, it is consistent to set $M_{f,N+1}$ to zero, where $f \leq N$. Similarly, it is consistent to set
\( B_f = 0, \ f \leq N \). So we take the \( M \) and \( B \) fields to have the form:

\[
M = \begin{pmatrix} M & 0 \\ 0 & m \end{pmatrix}, \quad B_f = \begin{pmatrix} 0 \\ \cdots \\ B \end{pmatrix}, \quad \tilde{B}_f = \begin{pmatrix} 0 \\ \cdots \end{pmatrix}.
\]

(16.27)

Consider the equation \( \partial W / \partial m = 0 \). This yields:

\[
(\det M - \tilde{B}B) = m\Lambda_0^b
\]

(16.28)

or

\[
(\det M - \tilde{B}B) = m\Lambda_0^b = \Lambda_{N_f}^{2N}. \tag{16.29}
\]

In the last line, we have used the relation between the \( \Lambda \) parameter of the theory with \( N_f \) quarks and that with \( N_f + 1 \) flavors. This is precisely the expression for the quantum modified moduli space of the \( N \)-flavor theory. Decoupling works perfectly here.

16.4 \( N_f > N + 1 \)

The case \( N_f > N + 1 \) poses new challenges. We might try to generalize our analysis of the previous section. Take, for example, \( N_f = N + 2 \). Then the baryons are in the second-rank antisymmetric tensor representations of the \( SU(N_f) \) gauge groups, \( B_{f\bar{g}}, \tilde{B}_{f\bar{g}} \). If we write a term in the superpotential

\[
W \sim B_{f\bar{g}} \tilde{B}_{k\bar{l}} M^{f\bar{k}} M^{g\bar{l}} \tag{16.30}
\]

this does not respect the non-anomalous \( R \) symmetry.

Seiberg suggested a different equivalence. The baryons, in general, have \( \tilde{N} = N_f - N \) indices. So baryons in the same representation of the flavor group can be constructed in a theory with gauge group \( SU(\tilde{N}) \) and quarks \( q_f, \bar{q}_f \) in the fundamental representation. Seiberg postulated that, in the infrared, this theory is dual to the original theory. This is not quite enough. One needs to add a set of gauge-singlet meson fields, \( M_{f\bar{f}} \), with superpotential:

\[
W = q^f \bar{q} \tilde{M}_{\bar{f}f} q^f. \tag{16.31}
\]

To check this picture, we can first check that the symmetries match. There is an obvious \( SU(N_f)_L \times SU(N_f)_f \times U(1)_B \). There is also a non-anomalous \( U(1)_R \) symmetry. It is important that the dual theory not be asymptotically free, i.e. that it is weakly coupled in the infrared. This is the case \( N > 3N_f/2 \). So again, this duality can only apply for a range of \( N_f, N \).
There are a number of checks on the consistency of this picture. Holomorphic decoupling is again one of the most persuasive. Take the case \( N_f = N + 2 \), so that the dual gauge group is \( SU(2) \). In this case, working in the flat directions of the \( SU(2) \) theory, one can do an instanton computation. One finds a contribution to the superpotential:

\[
W_{\text{inst}} = \det M.
\]  

(16.32)

This is consistent with all of the symmetries; it is not difficult to see that one can close up all of the fermion zero modes with elements of \( M \) and \( q \). So one has a superpotential:

\[
\int d^2 \theta (q M \bar{q} - \det M).
\]  

(16.33)

16.5 \( N_f \geq 3/2N \)

We have noted that Seiberg’s duality can’t persist beyond \( N_f = 3/2N \). Seiberg also made a proposal for the behavior of the theory in this regime: for \( 3/2N \leq N_f \leq 3N \), the theories are conformally invariant. Our Banks–Zaks fixed point lies in one corner of this range. As a further piece of evidence, consider the dimension of the operator \( \bar{Q} Q \). Under the non-anomalous \( R \)-symmetry,

\[
Q \to e^{i \alpha \frac{N_f - N}{2N_f}} Q.
\]  

(16.34)

If the theory is superconformal, the dimension of this chiral operator satisfies \( d = 3/2R \). As explained in Appendix D, the exact beta function of the theory is:

\[
\beta = -\frac{g^3}{16\pi^2} \frac{3N - N_F + N_f \gamma(g^2)}{1 - N(g^2/8\pi^2)}.
\]  

(16.35)

By assumption, this is zero, so

\[
\gamma = -\frac{3N - N_f}{N_f}.
\]  

(16.36)

The dimension of \( \bar{Q} Q \) is \( 2 + \gamma \), which is precisely \( 3/2R \).

We will not pursue this subject further, but there is further evidence one can provide for all of these dualities. They can also be extended to other gauge groups.

Suggested reading

The original papers of Seiberg (1994a,b, 1995a,b; see also Seiberg and Witten 1994) are quite accessible and essential reading on these topics, as is the review by Intriligator and Seiberg (1996). Good introductions are provided by the lecture

Exercises

1. Discuss the renormalization of the composite operator $\bar{Q}Q$, and verify that the relation $d = 3/2R$ is again satisfied.

2. Check the anomaly cancellation for the case $N_f = N + 1$. You may want to use an algebraic manipulation program, like Maple or Mathematica, to expedite the algebra.
An introduction to general relativity

Even as the evidence for the Standard Model became stronger and stronger in the 1970s and beyond, so the evidence for general relativity grew in the latter half of the twentieth century. Any discussion of the Standard Model and physics beyond must confront Einstein’s theory at two levels. First, general relativity and the Standard Model are very successful at describing the history of the universe and its present behavior on large scales. General relativity gives rise to the big bang theory of cosmology, which, coupled with our understanding of atomic and nuclear physics, explains – indeed predicted – features of the observed universe. But there are features of the observed universe which cannot be accounted for within the Standard Model and general relativity. These include the dark matter and the dark energy, the origin of the asymmetry between matter and antimatter, the origin of the seeds of cosmic structure (inflation), and more. Apart from these observational difficulties, there are also serious questions of principle. We cannot simply add Einstein’s theory onto the Standard Model. The resulting structure is not renormalizable, and cannot represent in any sense a complete theory. In this book we will encounter both of these aspects of Einstein’s theory. Within extensions of the Standard Model, in the next few chapters, we will attempt to explain some of the features of the observed universe. The second, more theoretical, level, is addressed in the third part of this book. String theory, our most promising framework for a comprehensive theory of all interactions, encompasses general relativity in an essential way; some would even argue that what we mean by string theory is the quantum theory of general relativity.

The purpose of this chapter is to introduce some of the concepts and formulas that are essential to the applications of general relativity in this text. No previous knowledge of general relativity is assumed. We will approach the subject from the perspective of field theory, focussing on the dynamical degrees of freedom and the equations of motion. We will not give as much attention to the beautiful – and conceptually critical – geometric aspects of the subject, though we will return to
An introduction to general relativity

Einstein put forward his principle of relativity in 1905. At that time, one might quip that half the known laws, those of electricity and magnetism, already satisfied this principle, with no modification. The other half, Newton’s laws, did not. In considering how one might reconcile gravitation and special relativity, Einstein was guided by the observed equality of gravitational and inertial mass. Inertia has to do with how objects move in space-time in response to forces. Operationally, the way we define space-time – our measurements of length, time, energy and momentum – depends crucially on this notion. The fact that gravity couples to precisely this mass suggests that gravity has a deep connection to the nature of space-time. Considering this equivalence, Einstein noted that an observer in a freely falling elevator (in a uniform gravitational field) would write down the same laws of nature as an observer in an inertial frame without gravity. Consider, for example, an elevator full of particles interacting through a potential $V(\mathbf{x}_i - \mathbf{x}_j)$. In the inertial frame,

$$m \frac{d^2 \mathbf{x}_i}{dt^2} = m \mathbf{g} - \nabla_i V(\mathbf{x}_i - \mathbf{x}_j).$$  \hspace{1cm} (17.1)

The coordinates of the accelerated observer are related to those of the inertial observer by

$$\mathbf{x}_i = \mathbf{x}'_i + \frac{1}{2} \mathbf{g} t^2$$  \hspace{1cm} (17.2)

so, plugging in the equations of motion:

$$m \frac{d^2 \mathbf{x}'_i}{dt^2} = -\nabla_i V(\mathbf{x}'_i - \mathbf{x}'_j).$$  \hspace{1cm} (17.3)

Einstein abstracted from this thought experiment a strong version of the equivalence principle: the equations of motion should have the same form in any frame, inertial or not. In other words, it should be possible to write the laws so that in two coordinate systems, $x^\mu$ and $x'^\mu(x)$, they take the same form. This is a strong requirement. We will see that it is similar to gauge invariance, where the requirement that the laws take the same form after gauge transformations determines the dynamics.

### 17.1 Tensors in general relativity

To implement the equivalence principle, we begin by thinking about the invariant element of distance. In an inertial frame, in special relativity

$$ds^2 = d\mathbf{x}^2 - dt^2 = \eta_{\mu\nu}dx^\mu dx^\nu.$$  \hspace{1cm} (17.4)
Note here that we have changed the sign of the metric, as we said we would do, from that used earlier in this text. This is the convention of most workers and texts in general relativity and string theory. The coordinate transformation above for the accelerated observer alters the line element. This suggests we consider the generalization:

\[ ds^2 = g_{\mu\nu}(x)dx^\mu dx^\nu. \] (17.5)

The metric tensor, \( g_{\mu\nu} \), will encode the dynamics and physical effects of gravitation. We will know that there is a non-trivial gravitational field when we cannot find coordinates which make \( g_{\mu\nu} = \eta_{\mu\nu} \) everywhere.

To develop a dynamical theory, we would like to write invariant actions (which will yield covariant equations). This problem has two parts. We need to couple the fields we already have to the metric in an invariant way. We also require the analog of the field strength for gravity, which will determine the dynamics of \( g_{\mu\nu} \) in much the same way as \( F_{\mu\nu} \) determines the dynamics of \( A_\mu \). This object is the Riemann tensor, \( R_{\mu\nu\rho\sigma} \). We will see later that the formal analogy can be made very precise, with an object, the spin connection \( \omega_\mu \), constructed out of the metric tensor, playing the role of \( A_\mu \). The close analogy will also be seen when we discuss Kaluza–Klein theories, where higher-dimensional general coordinate transformations become the lower-dimensional gauge transformations.

We first describe how derivatives and \( g_{\mu\nu} \) transform under coordinate transformations. Writing

\[ x^\mu = x^\mu(x') \] (17.6)

we have

\[ \partial_\rho' \phi(x') = \frac{\partial x^\rho}{\partial x^\mu'} \partial_\rho \phi(x) = \Lambda^\rho_\mu(x) \partial_\rho \phi(x). \] (17.7)

An object which transforms like \( \partial_\rho \phi \) is said to be a covariant vector. An object which transforms like \( \partial_\rho \phi \partial_\rho \phi \ldots \partial_\rho \phi \) is said to be an \( n \)th rank covariant tensor; \( g_{\mu\nu} \) is an important example of a tensor. We can obtain the transformation law for \( g_{\mu\nu} \) from the invariance of the line element:

\[ g'_{\mu\nu}dx'^\mu dx'^\nu = g_{\mu\nu} \frac{\partial x^\mu}{\partial x^\rho'} \frac{\partial x^\nu}{\partial x^\sigma'} dx^\rho' dx^\sigma'. \] (17.8)

So

\[ g'_{\mu\nu} = g_{\rho\sigma} \frac{\partial x^\rho}{\partial x^\mu'} \frac{\partial x^\sigma}{\partial x^\nu'}. \] (17.9)

Now \( dx^\mu \) transforms with the inverse of \( \Lambda \):

\[ dx'^\mu = \frac{\partial x'^\mu}{\partial x^\rho} dx^\rho, \] (17.10)
An introduction to general relativity

where \( dx^\mu \) is said to be a “contravariant” vector. Indices can be raised and lowered with \( g_{\mu\nu} \); \( g_{\mu\nu} V^\nu \) transforms like a covariant vector, for example.

Another important object is the volume element, \( d^4x \). Under a coordinate transformation,

\[
d^4x = \left| \frac{\partial x}{\partial x'} \right| d^4x'.
\]

(17.11)

The object in between the vertical lines is the Jacobian of the coordinate transformation, \(|\text{det}\Lambda|\). The quantity \( \sqrt{-\text{det}(g)} \) transforms in exactly the opposite fashion. So

\[
\int d^4x \sqrt{-\text{det}(g)},
\]

(17.12)

the proper four-volume is invariant.

Let’s consider a real scalar field, \( \phi \). The action, before including gravity, is

\[
S = \int d^4x \left[ \frac{1}{2} \left( -\partial_\mu \phi \partial_\nu \phi \eta_{\mu\nu} - m^2 \phi^2 \right) \right].
\]

(17.13)

To make this invariant, we can replace \( \eta_{\mu\nu} \) by \( g_{\mu\nu} \), and include a factor \( \sqrt{\text{det}(-g)} \) along with the \( d^4x \). So

\[
S = \int d^4x \sqrt{\text{det}(-g)} \left[ \frac{1}{2} \left( -\partial_\mu \phi \partial_\nu \phi g_{\mu\nu} - m^2 \phi^2 \right) \right].
\]

(17.14)

The equations of motion should be covariant. They must generalize the equation

\[
\partial^2 \phi = -V'(\phi).
\]

(17.15)

The first derivative of \( \phi \), we have seen, transforms as a vector, \( V_\mu \), under coordinate transformations, but the second derivative does not transform simply:

\[
\partial_\mu V_\nu = \partial_\mu \left( \frac{\partial x^{\rho'}}{\partial x^v} V_\rho' \right)
= \frac{\partial x^{\rho'}}{\partial x^v} \frac{\partial x^{\sigma'}}{\partial x^\mu} \partial_\sigma V_\rho' + \frac{\partial^2 x^{\rho'}}{\partial x^\mu \partial x^v} V_\rho.
\]

(17.16)

To compensate for the extra, inhomogeneous term, we need a covariant derivative, as in gauge theories. Rather than look at the equations of motion directly, however, we can integrate by parts in the scalar field Lagrangian so as to obtain second derivatives. This yields:

\[
\sqrt{-g} (g^{\mu\nu} \partial_\mu \partial_\nu \phi + \partial_\mu g^{\mu\nu} \partial_\nu \phi) + g^{\mu\nu} \partial_\mu \sqrt{-g} \partial_\nu \phi.
\]

(17.17)

To bring this into a convenient form, we need a formula for the derivative of a determinant. We can work this out using the same trick we have used repeatedly in
the case of the path integral. Write:

\[
\det(M) = \exp(\text{Tr} \ln(M))
\]

so

\[
\det(M + \delta M) \approx \exp(\text{Tr} \ln(M) + \ln(1 + M^{-1}\delta M)) = \det(M)(1 + M^{-1}\delta M).
\]

(17.19)

So, for example,

\[
\frac{d \det(M)}{dM_{ij}} = M^{-1}_{ij} \det(M).
\]

(17.20)

Putting this all together, we have the quadratic term in the action for the scalar field:

\[
\phi \left( g^{\mu\nu} \partial_\mu \partial_\nu \phi + \partial_\mu g^{\mu\nu} \partial_\nu \phi + g^{\mu\nu} \frac{1}{2} g^{\rho\sigma} \partial_\mu g_{\rho\sigma} \partial_\nu \phi \right).
\]

(17.21)

Writing this as

\[
\phi g^{\mu\nu} D_\mu \partial_\nu \phi,
\]

(17.22)

we have for the covariant derivative

\[
D_\mu V_\nu = \partial_\mu V_\nu - \Gamma^\lambda_{\mu\nu} V_\lambda.
\]

(17.23)

Here

\[
\Gamma^\lambda_{\mu\nu} = \frac{1}{2} g^{\lambda\rho} \left( \partial_\mu g_{\rho\nu} + \partial_\nu g_{\rho\mu} - \partial_\rho g_{\mu\nu} \right).
\]

(17.24)

Note that \( \Gamma^\lambda_{\mu\nu} \) is symmetric in \( \mu, \nu \). The covariant derivative is often denoted by a semicolon and a Greek letter in the subscript or superscript:

\[
D_\mu V_\nu = V_{\mu;\nu}.
\]

(17.25)

The reader can check that

\[
\Gamma^\lambda_{\mu\nu} = \Gamma^\lambda_{\nu\mu} - \frac{\partial^2 x^\lambda}{\partial x^\mu \partial x^\nu}.
\]

(17.26)

which just compensates the extra term in the transformation law. Here \( \Gamma \) is known as the affine connection (the components of \( \Gamma \) are also sometimes referred to as the Christoffel symbols, and \( \Gamma \) as the Christoffel connection; it is sometimes written as \( \{ \mu^\nu_{\rho} \} \)). With this definition:

\[
D_\mu V_\nu = \partial_\mu V_\nu - \Gamma^\lambda_{\mu\nu} V_\lambda
\]

(17.27)
transforms like a tensor with two indices, $V_{\mu \nu}$. Similarly, acting on contravariant vectors:

$$D_{\mu} V^{\nu} = \partial_{\mu} V^{\nu} + \Gamma^{\nu}_{\mu \lambda} V^{\lambda}$$  \hspace{1cm} (17.28)

transforms properly. You can also check that $V_{\mu ; \nu \rho}$ transforms as a third-rank covariant tensor, and so on.

To get some practice, and to see how the metric tensor can encode gravity, let’s use the covariant derivative to describe the motion of a free particle. In an inertial frame, without gravity,

$$\frac{d^2 x^\mu}{d \tau^2} = 0.$$  \hspace{1cm} (17.29)

We make this equation covariant by first rewriting it as:

$$\frac{dx^\rho}{d\tau} \frac{\partial}{\partial x^\rho} \left( \frac{d x^\mu}{d \tau} \right).$$  \hspace{1cm} (17.30)

We need to replace the derivative of the vector in the last term by a covariant derivative. The covariant version of the equation is:

$$\frac{dx^\rho}{d\tau} D_{\rho} \left( \frac{\partial x^\mu}{\partial \tau} \right) = \frac{\partial x^\rho}{\partial \tau} \frac{\partial^2 x^\mu}{\partial x^\rho \partial \tau} + \Gamma^\rho_{\rho \sigma} \frac{\partial x^\sigma}{\partial \tau} \frac{\partial x^\rho}{\partial \tau}.$$  \hspace{1cm} (17.31)

So the equation of motion is:

$$\frac{d^2 x^\mu}{d \tau^2} + \Gamma^\mu_{\rho \sigma} \frac{\partial x^\sigma}{\partial \tau} \frac{\partial x^\rho}{\partial \tau} = 0.$$  \hspace{1cm} (17.33)

This is known as the geodesic equation. Viewed as Euclidean equations, the solutions are geodesics. For a sphere embedded in flat three-dimensional space, for example, the solutions of this equation are easily seen to be great circles. We should be able to recover Newton’s equation for a weak gravitational field. For a weak, static gravitational field we might expect

$$g_{\mu \nu} = \eta_{\mu \nu} + h_{\mu \nu}$$  \hspace{1cm} (17.34)

with $h_{\mu \nu}$ small. Since the gravitational potential in Newton’s theory is a scalar, we might further guess:

$$g_{00} = -(1 + 2 \phi) \quad g_{ij} = \delta_{ij}$$  \hspace{1cm} (17.35)

Then the non-vanishing components of the affine connection are:

$$\Gamma^i_{00} = \frac{1}{2} g^{ij} \left[ \partial_0 g_{i0} + \partial_0 g_{0i} - \partial_i g_{00} \right] = \partial_i \phi.$$  \hspace{1cm} (17.36)
\[ \Gamma^0_{0i} = -\partial_i \phi. \] (17.37)

In the non-relativistic limit, we can replace \( \tau \) by \( t \), and we have the equation of motion:
\[ \frac{d^2x_i}{dt^2} = -\partial_i \phi. \] (17.38)

## 17.2 Curvature

Using the covariant derivative, we can construct actions for scalars and gauge fields. Fermions require some additional machinery; we will discuss this towards the end of the chapter. Instead, we turn to the problem of finding an action for the gravitational field itself. In the case of gauge fields, the crucial object was the field strength, \( F_{\mu\nu} = [D_{\mu}, D_{\nu}] \). For the gravitational field, we will also work with the commutator of covariant derivatives. We write
\[ [D_\mu, D_\nu] V_\rho = \mathcal{R}^\sigma_{\rho\mu\nu} V_\sigma, \] (17.39)

where \( \mathcal{R} \) is known as the curvature tensor. For a Euclidean space, it measures what we would naturally call the curvature of the space. It is straightforward to work out an expression for \( \mathcal{R} \) in terms of the affine connection:
\[ \mathcal{R}_\lambda^{\mu\nu\kappa} = \partial_\kappa \Gamma_\mu^{\lambda\nu} - \partial_\nu \Gamma_\mu^{\lambda\kappa} + \Gamma_\eta^{\lambda\nu} \Gamma_\mu^{\kappa\eta} - \Gamma_\mu^{\kappa\rho} \Gamma_\rho^{\lambda\nu}. \] (17.40)

Unlike \( F \), which is first order in derivatives of \( A \), \( \mathcal{R} \) is second order in derivatives of \( g \). As a result, the gravitational action will be first order in \( \mathcal{R} \).

Note that \( \mathcal{R} \) transforms as a tensor under coordinate transformations. It has important symmetry and cyclicity properties. These are most conveniently described by lowering the first index on \( \mathcal{R} \):
\[ \mathcal{R}_{\lambda\mu\nu\kappa} = \mathcal{R}_{\kappa\lambda\mu\nu}, \] (17.41)
\[ \mathcal{R}_{\lambda\mu\nu\kappa} = -\mathcal{R}_{\mu\lambda\nu\kappa} = -\mathcal{R}_{\lambda\mu\kappa\nu} = \mathcal{R}_{\mu\lambda\kappa\nu}, \] (17.42)
\[ \mathcal{R}_{\lambda\mu\nu\kappa} + \mathcal{R}_{\lambda\kappa\mu\nu} + \mathcal{R}_{\lambda\nu\kappa\mu} = 0. \] (17.43)

Starting with \( \mathcal{R} \), we can define other tensors. The most important is the Ricci tensor. This has two indices:
\[ \mathcal{R}_{\mu\kappa} = g^{\lambda\nu} \mathcal{R}_{\lambda\mu\nu\kappa}. \] (17.44)

\( \mathcal{R} \) is a symmetric tensor,
\[ \mathcal{R}_{\mu\kappa} = \mathcal{R}_{\kappa\mu}. \] (17.45)
Also very important is the Ricci scalar:

\[ \mathcal{R} = g^{\mu \kappa} \mathcal{R}_{\mu \kappa}. \]  

(17.46)

Note that \( \mathcal{R} \) also satisfies an important identity, similar to the Bianchi identity for \( F^{\mu \nu} \) (which gives the homogeneous Maxwell equations):

\[ \mathcal{R}_{\lambda \mu \nu \kappa ; \eta} + \mathcal{R}_{\lambda \mu \eta \nu ; \kappa} + \mathcal{R}_{\lambda \mu \kappa \eta ; \nu} = 0. \]  

(17.47)

17.3 The gravitational action

Having introduced, through the Riemann tensor, a description of curvature, we are in a position to write a generally covariant action for the gravitational field. Linear terms in \( \mathcal{R} \), as we noted, will be second order in the derivatives of the metric, so they can provide a suitable action. The action must be a scalar, so we take

\[ S_{\text{grav}} = \frac{1}{2\kappa^2} \int d^4x \sqrt{-g} \mathcal{R}. \]  

(17.48)

To obtain the equations of motion, we need to vary the complete action, including the parts involving matter fields, with respect to \( g_{\mu \nu} \). We first consider variation of the terms involving the matter fields. The variation of the matter action with respect to \( g_{\mu \nu} \) turns out to be nothing but the stress-energy tensor, \( T^{\mu \nu} \). Once one knows this fact, this is often the easiest way to find the stress–energy tensor for a system. To see that this identification is correct, we first show that \( T^{\mu \nu} \) is covariantly conserved, i.e.

\[ D_\nu T^{\nu \mu} = T^{\mu \nu}_{; \nu} = 0. \]  

(17.49)

By assumption, the fields solve the equations of motion in the gravitational background, so the variation of the action, for any variation of the fields, is zero. Consider, then, a space-time translation:

\[ x^{\mu'} = x^\mu + \epsilon^\mu. \]  

(17.50)

Starting with

\[ g'_{\mu \nu}(x') = \frac{\partial x^\rho}{\partial x^\mu} g_{\rho \sigma} \frac{\partial x^\sigma}{\partial x^\nu}, \]  

(17.51)

we have

\[ g'_{\mu \nu}(x + \epsilon) = g_{\mu \nu}(x) - \partial_\mu \epsilon^\rho g_{\rho \nu} - \partial_\nu \epsilon^\sigma g_{\sigma \mu}. \]  

(17.52)

So

\[ \delta g_{\mu \nu}(x) = -g_{\mu \lambda} \partial_\nu \epsilon^\lambda - g_{\nu \lambda} \partial_\mu \epsilon^\lambda - \partial_\lambda g_{\mu \nu} \epsilon^\lambda. \]  

(17.53)
Defining
\[
\frac{\delta S_{\text{matt}}}{\delta g_{\mu\nu}} = T^{\mu\nu}, \tag{17.54}
\]
under this particular variation of the metric we have:
\[
\delta S_{\text{matt}} = - \int d^4x \sqrt{-g} T^{\mu\nu} \left[ g_{\mu\lambda} \partial_\nu \epsilon^\lambda + g_{\lambda\nu} \partial_\mu \epsilon^\lambda + \partial_\lambda g_{\mu\nu} \epsilon^\lambda \right]. \tag{17.55}
\]
Integrating by parts on the first two terms, and using the symmetry of the metric (and consequently the symmetry of \(T^{\mu\nu}\)):
\[
\delta S_{\text{matt}} = \int d^4x \left[ \partial_\mu (T^{\mu\lambda} \sqrt{-g}) - \frac{1}{2} \partial_\lambda g_{\mu\nu} T^{\mu\nu} \sqrt{-g} \right] \epsilon^\lambda. \tag{17.56}
\]
The coefficient of \(\epsilon^\lambda\) vanishes for fields which obey the equations of motion. This object is \(T^{\mu\nu}_{\dot{\mu}}\). The reader can verify this last identification painstakingly, or by noting that:
\[
\Gamma^{\mu}_{\mu\lambda} = \frac{1}{\sqrt{-g}} \partial_\lambda \sqrt{-g} \tag{17.57}
\]
so, for a general vector, for example,
\[
V^{\mu}_{\dot{\mu}} = \frac{1}{\sqrt{-g}} \partial_\mu (\sqrt{-g} V^\mu), \tag{17.58}
\]
and similarly for higher-rank tensors.

As a check, consider the stress tensor for a free massive scalar field. Once more, the action is:
\[
S = \int d^4x \sqrt{-g} \left( -\frac{1}{2} g^{\mu\nu} \partial_\mu \phi \partial_\nu \phi - \frac{1}{2} m^2 \phi^2 \right). \tag{17.59}
\]
So, recalling our formula for the variation of the determinant:
\[
T_{\mu\nu} = \frac{1}{2} \partial_\mu \phi \partial_\nu \phi - \frac{1}{4} g_{\mu\nu} (g^{\rho\sigma} \partial_\rho \phi \partial_\sigma \phi - m^2 \phi^2). \tag{17.60}
\]
To find the full gravitational equations – Einstein’s equations – we need to vary also the gravitational term in the action. This is best done by explicitly constructing the variation of the curvature tensor under a small variation of the field. We leave the details for the exercises, and quote the final result:
\[
\mathcal{R}_{\mu\nu} - \frac{1}{2} g_{\mu\nu} \mathcal{R} = \kappa^2 T_{\mu\nu}. \tag{17.61}
\]
We will consider many features of this equation, but it is instructive to see how we obtain Newton’s expression for the gravitational field, in the limit that gravity is
not too strong. We have already argued that in this case we can write

$$g_{00} = -(1 + 2\phi) \quad g^{ij} = \delta_{ij}.$$  \hfill (17.62)

As we have seen, the non-vanishing components of the connection are:

$$\Gamma^i_00 = \partial_i \phi \quad \Gamma^0_0i = -\partial_i \phi.$$  \hfill (17.63)

Correspondingly, the non-zero components of the curvature tensor are:

$$R^i_{00j} = \partial_i \partial_j \phi = -R^i_{0j0} = R^0_{ij0}$$  \hfill (17.64)

where the relations between the various components follow from the symmetries of the curvature tensor. From these we can construct the Ricci tensor and the Ricci scalar:

$$\mathcal{R}_{00} = \nabla^2 \phi \quad \mathcal{R} = -\nabla^2 \phi.$$  \hfill (17.65)

So we obtain

$$-\nabla^2 \phi = \kappa^2 T_{00}.$$  \hfill (17.66)

Note, from this, we can identify Newton’s constant in terms of $\kappa$,

$$G_N = \frac{\kappa^2}{8\pi}.$$  \hfill (17.67)

### 17.4 The Schwarzschild solution

Not long after Einstein wrote down his equations for general relativity, Schwarzschild constructed the solution of the equations for a static, isotropic metric. Such a metric can be taken to have the form:

$$ds^2 = -B(r) dt^2 + A(r) dr^2 + r^2 (d\theta^2 + \sin^2 \theta d\phi^2).$$  \hfill (17.68)

Actually, rotational invariance would allow other terms. In terms of vectors, $d\vec{x}$, the most general metric has the form

$$-B(r) dt^2 + D(r) \vec{x} \cdot d\vec{x} dt + C(r) d\vec{x} \cdot d\vec{x} + D(r) (\vec{x} \cdot d\vec{x})^2.$$  \hfill (17.69)

By a sequence of coordinate transformations, however, one can bring the metric to the form above.

We will solve Einstein’s equations with $T_{\mu\nu} = 0$. Corresponding to $ds^2$, we have the non-vanishing metric components:

$$g_{rr} = A(r) \quad g_{\phi \phi} = r^2 \sin^2 \theta \quad g_{tt} = -B(r) \quad g_{\theta \theta} = r^2.$$  \hfill (17.70)
Our goal is to determine $A$ and $B$. The equations for $A$ and $B$ follow from Einstein’s equations. We first need to evaluate the non-vanishing Christoffel symbols. This is done in the exercises. While straightforward, the calculation of the connection and the curvature is slightly tedious, and this is an opportunity to practice with the computer packages described in the exercises. The non-vanishing components of the affine connection are:

\[
\Gamma^r_{rr} = \frac{1}{2A(r)} A'(r) \quad \Gamma^r_{\theta \theta} = -\frac{r}{A(r)} \quad \Gamma^r_{\phi \phi} = -\frac{r \sin^2(\theta)}{A(r)}
\]

\[
\Gamma^r_{\phi \phi} = \frac{r \sin^2 \theta}{A(r)} \quad \Gamma^r_{tt} = \frac{1}{2A(r)} B'(r),
\]

where the primes denote derivatives with respect to $r$. Similarly

\[
\Gamma^\theta_{r \phi} = \Gamma^\theta_{\phi r} = \frac{1}{r} \quad \Gamma^\phi_{\phi \theta} = -\sin(\theta) \cos(\theta)
\]

\[
\Gamma^\phi_{\phi r} = \Gamma^\phi_{r \phi} = \frac{1}{r} \quad \Gamma^\phi_{\theta \phi} = \Gamma^\phi_{\phi \theta} = \cos(\theta)
\]

\[
\Gamma^t_{tr} = \Gamma^t_{rt} = \frac{B'}{2B}.
\]

The non-vanishing components of the Ricci tensor are:

\[
R_{rr} = \frac{B''}{2B} - \frac{1}{4} \frac{B''}{B} \left( \frac{A'}{A} + \frac{B'}{B} \right) - \frac{1}{r} \frac{A'}{A}
\]

\[
R_{\theta \theta} = -1 + \frac{r}{2A} \left( -\frac{A'}{A} + \frac{B'}{B} \right) + \frac{1}{A}
\]

\[
R_{\phi \phi} = \sin^2 \theta R_{\theta \theta} \quad R_{tt} = -\frac{B''}{2A} + \frac{1}{4} \frac{B'}{A} \left( \frac{A'}{A} + \frac{B'}{B} \right) - \frac{1}{r} \frac{B'}{A}.
\]

For empty space, Einstein’s equation reduces to

\[
R_{\mu \nu} = 0.
\]

We will require that asymptotically, the space-time is just flat Minkowski space, so we will solve these equations with the requirement

\[
A_{r \to \infty} = B_{r \to \infty} = 1.
\]

Examining the components of the Ricci tensor, we see that it is enough to set $R_{rr} = R_{\theta \theta} = R_{tt} = 0$. We can simplify the equations with a little cleverness:

\[
\frac{R_{rr}}{A} + \frac{R_{tt}}{B} = -\frac{1}{r A} \left( \frac{A'}{A} + \frac{B'}{B} \right).
\]
From this it follows that $A = 1/B$. Then, from $R_{\theta\theta} = 0$, we have

$$
\frac{d}{dr}(rB) - 1 = 0. 
$$

(17.79)

So

$$
rB = r + \text{const}. 
$$

(17.80)

Now $B = -g_{tt}$, so, far away, where the space-time is nearly flat, $B = 1 + 2\phi$, where $\phi$ is the gravitational potential. So:

$$
B(r) = \left[1 - \frac{2MG}{r}\right] \quad A(r) = \left[1 - \frac{2MG}{r}\right]^{-1}. 
$$

(17.81)

### 17.5 Features of the Schwarzschild metric

So finally, we have the Schwarzschild metric:

$$
ds^2 = -\left[1 - \frac{2MG}{r}\right]dt^2 + \left[1 - \frac{2MG}{r}\right]^{-1}dr^2 + r^2 d\theta^2 + r^2 \sin^2 \theta d\phi^2.
$$

(17.82)

Far away, this clearly describes an object of mass $M$. While we have so far discussed the energy–momentum tensor for matter, we have not discussed the energy of gravitation. The situation is similar to the problem of defining charge in a gauge theory. There, the most straightforward definition involves using the asymptotic behavior of the fields to determine the total charge. In gravity, the energy is similar. There is no invariant local definition of the energy density. But in spaces that are asymptotically flat, one can give a global notion of the energy, known as the ADM (for Arnowitt, Deser and Misner) energy. Only the $1/r$ behavior of the fields enters. We will not review this here, but, not surprisingly, in the present case, this energy, $P^0$, is equal to $M$.

The curvature of space-time near a star yields observable effects. Einstein, when he first published his theory, proposed two tests of the theory: the bending of light by the Sun, and the precession of Mercury’s perihelion. In the latter case, the theory accounted for a known anomaly in the motion of the planet; the prediction of the bending of light was soon measured.

A striking feature of this metric is that it becomes singular at a particular value of $r$, known as the Schwarzschild radius (horizon),

$$
r_h = 2MG. 
$$

(17.83)

At this point, the coefficient of $dr^2$ diverges, and that of $dt^2$ vanishes. Both change sign, in some sense reversing the roles of $r$ and $t$. This singularity is a bit of a fake. No component of the curvature becomes singular. One can exhibit this by choosing
17.5 Features of the Schwarzschild metric

coordinates in which the metric is completely non-singular (see the exercises at the end of the chapter).

For most realistic objects, such as planets and typical stars, this $r_h$ is well within the star, where surely it is important to use a more realistic model of $T_{\mu\nu}$. But there are systems in nature where the “material” lies well within the Schwarzschild radius. These systems are known as black holes. The known black holes arise from the collapse of very massive stars. It is conceivable that smaller black holes arise from more microscopic processes. These systems have striking properties. Classically, light cannot escape from within the horizon; the curvature singularity at the origin is real. Black holes are nearly featureless. Classically, an external observer can only determine the mass, charge and angular momentum of the black hole, however complex the system which may have preceded it.

Bekenstein pointed out that the horizon area has peculiar properties, and behaves much like a thermal system. Most importantly, it obeys a relation analogous to the second law,

$$dA > 0.$$  \hspace{1cm} (17.84)

Identifying the area with an entropy suggests that one can associate a temperature with the black hole, known as the Hawking temperature. The black hole horizon is a sphere of area $4\pi r_h^2$. So one might guess, on dimensional grounds,

$$T_h = \frac{1}{8\pi GM}.$$  \hspace{1cm} (17.85)

The precise constant does not follow from this argument. The reader is invited to work through a heuristic, path integral derivation in the exercises.

Quantum mechanically, Hawking showed that this temperature has a microscopic significance. When one studies quantum fields in the gravitational background, one finds that particles escape from the black hole. These particles have a thermal spectrum, with a characteristic temperature $T_h$.

These features of black holes raise a number of conceptual questions. For the black hole at the center of the galaxy, for example, with mass millions of times greater than the Sun, the Hawking temperature is ludicrously small. Correspondingly, the Hawking radiation is totally irrelevant. But one can imagine microscopic black holes which would evaporate in much more modest periods of time. This raises a puzzle. The Hawking radiation is strictly thermal. So one could form a black hole, say, in the collapse of a small star. The initial star is a complex system, with many features. The black hole is nearly featureless. Classically, however, one might imagine that some memory of the initial state of the system is hidden behind the horizon; this information would simply be inaccessible to the external observer. But owing to the evaporation, the black hole, and its horizon, eventually
disappear. One is left with just a thermal bath of radiation, with features seemingly determined by the temperature (and therefore the mass). Hawking suggested that this information paradox posed a fundamental challenge for quantum mechanics: pure states could evolve into mixed states, through the formation of a black hole. For many years, this question was the subject of serious debate. One might respond to Hawking’s suggestion by saying that the information is hidden in subtle correlations in the radiation, as would be the case of burning, say, a lump of coal initially in a pure state. But more careful consideration indicates that things cannot be quite so simple. Only in relatively recent years has string theory provided at least a partial resolution of this paradox. We will touch on this subject briefly in the chapters on string theory. In the suggested reading, the reader will be referred to more thorough treatments.

17.6 Coupling spinors to gravity

In any theory which will ultimately describe nature, both spinors and general relativity will be present. Coupling spinors to gravity requires some concepts beyond those we have utilized up to now. The usual covariant derivative is constructed for tensors under changes of coordinates. In flat space, spinors are defined by their properties under rotations – more generally Lorentz transformations. To do the same in general relativity, it is necessary, first, to introduce a local Lorentz frame at each point. The basis vectors in this frame are denoted $e^a_\mu$. Here $\mu$ is the Lorentz index; we can think of $a$ as labeling the different vectors. The $e_\mu$'s, in four dimensions, are referred to as a tetrad or “vierbein.” In other dimensions, these are called vielbein.

Requiring that the basis vectors be orthonormal, in the Lorentzian sense, gives

$$e^a_\mu(x)e_{av}(x) = g_{\mu v}(x)$$  \hspace{1cm} (17.86)

or, equivalently,

$$e^a_\mu(x)e^{b\mu}(x) = \eta^{ab}.$$  \hspace{1cm} (17.87)

The choice of the vielbein is not unique. We can multiply $e$ by a Lorentz matrix, $\Lambda^a_b(x)$. Using $e$, we can change indices from space-time (sometimes called “world”) indices to tangent space indices:

$$V^a = e^a_\mu V^\mu.$$  \hspace{1cm} (17.88)

Using this, we can figure out what is the form of the connection which maintains the gauge symmetry. We require:

$$D_\mu V^a = e^{av} D_\mu V_v.$$  \hspace{1cm} (17.89)
The derivative on the left-hand side is:

\[
(\partial_\mu V^a + (\omega_\mu)_b^a V^b)
\]  

(17.90)

With a bit of work, one can find explicitly the connection between the spin connection and the vielbein:

\[
\omega_{\mu}^{ab} = \frac{1}{2} e^{va} (\partial_\mu e_v^b - \partial_v e_\mu^b) - \frac{1}{2} e^{vb} (\partial_\mu e_v^a - \partial_v e_\mu^a) - \frac{1}{2} e^{p\sigma} e^{\rho c} (\partial_\rho e_{\sigma c} - \partial_{\sigma} e_{\rho c}) e_{\mu}^c.
\]

(17.91)

Now we put this together. First, the curvature has a simple expression in terms of the spin connection, which formally is identical to that of a Yang–Mills connection:

\[
(R_{\mu\nu})_b^a = \partial_\mu (\omega_{\nu})_b^a - \partial_\nu (\omega_{\mu})_b^a + [\omega_{\mu}, \omega_{\nu}]_b^a.
\]

(17.92)

This is connected simply to the Riemann tensor:

\[
(R_{\mu\nu})_b^a = e^a_{\sigma} e^\tau_{b} (R_{\mu\nu})_{\sigma}^\tau.
\]

(17.93)

We can now construct, also, a generally covariant action for spinors:

\[
\int d^D x \sqrt{g} i \bar{\psi} \Gamma^a_\mu e^\mu_a \left( \partial_\mu + \frac{1}{2} \omega_{\mu}^{bc} \Sigma_{bc} \right) \psi.
\]

(17.94)

**Suggested reading**

There are a number of excellent textbooks on general relativity, for example those of Weinberg (1972), Wald (1984), Carroll (2004) and Hartle (2003). Many aspects of general relativity important for string theory are discussed in the text of Green et al. (1987). A review of black holes in string theory is provided by Peet (2000).

**Exercises**

1. Show that \( g^{\mu\nu} \partial_\nu \) transforms like \( dx^\mu \). Verify explicitly that the covariant derivative of a vector transforms correctly.
2. Derive Eq. (17.38) by considering the action for a particle:

\[
S = -\int ds = -\int \sqrt{-g_{\mu\nu} \frac{dx^\mu}{d\tau} \frac{dx^\nu}{d\tau}}.
\]

(17.95)

3. Verify the formula, Eq. (17.40) for \( \mathcal{R} \), its symmetry properties, and the Bianchi identities.
4. Repeat the derivation of the conservation of the stress tensor, being careful with all of the steps. Derive the stress tensor for the Maxwell field of electrodynamics, \( F_{\mu\nu} \). Derive Einstein’s equations from the action. You’ll want to show first that

\[
\delta R_{\mu\nu} = (\delta \Gamma^\lambda_{\mu\lambda})_{;\nu} - (\delta \Gamma^\lambda_{\mu\nu})_{;\lambda}.
\]
(5) Download a package of programs for doing calculations in general relativity in Maple, Mathematica, or any other program you prefer. A Google search will yield several choices. Practice by computing the components of the affine connection and the curvature for the Schwarzschild solution.

(6) Heuristic derivation of the Hawking temperature: near the horizon, one can choose coordinates so that the metric is almost flat. Check that with
\[ \eta = 2\sqrt{r_h(r - r_h)} \]
\[ ds^2 = -4r_h^2\eta^2 dt^2 + d\eta^2 + r_h^2 d\Omega_2^2. \]

Now take the time to be Euclidean, \( t \rightarrow i\phi/(2r_h) \). Check that now this is of the metric of the plane times that of a two sphere, provided that \( \phi \) is an angle, \( 0 < \phi < 2\pi \) (otherwise, the space is said to have a conical singularity). Argue that field theory on this sphere is equivalent to field theory at finite temperature, with temperature \( T_h \) (you may need to read Appendix C, particularly the discussion of finite temperature field theory).
Very quickly after Einstein published his general theory, a number of researchers attempted to apply Einstein’s equations to the universe as a whole. This was a natural, if quite radical, move. In Einstein’s theory, the distribution of energy and momentum in the universe determines the structure of space-time, and this applies as much to the universe as a whole as to the region of space, say, around a star. To get started these early researchers made an assumption which, while logical, may seem a bit bizarre. They took the principles enunciated by Copernicus to their logical extreme, and assumed that space-time was homogeneous and isotropic, i.e. that there is no special place or direction in the universe. They had virtually no evidence for this hypothesis at the time – definitive observations of galaxies outside of the Milky Way were only made a few years later. It was only decades later that evidence in support of this cosmological principle emerged. As we will discuss, we now know that the universe is extremely homogeneous, when viewed on sufficiently large scales.

To implement the principle, just as, for the Schwarzschild solution, we begin by writing the most general metric consistent with an assumed set of symmetries. In this case, the symmetries are homogeneity and isotropy in space. A metric of this form is called Friedmann–Robertson–Walker (FRW). We can derive this metric by imagining our three-dimensional space, at any instant, as a surface in a four-dimensional space. There should be no preferred direction on this surface; in this way, we will impose both homogeneity and isotropy. The surface will then be one of constant curvature. Consider, first, the mathematics required to describe a 2 + 1-dimensional space-time of this sort. The three spatial coordinates would satisfy

\[ x_1^2 + x_2^2 = k(R^2 - X_3^2), \]  

(18.1)

where \( k = \pm 1 \) might be positive or negative, corresponding to a space of positive
or negative curvature. Then the line element on the surface is (for positive $k$):
\[
\text{d}x^2 = dx_1^2 + dx_2^2 + dx_3^2 = dx_1^2 + dx_2^2 + \frac{(x_1 dx_1 + x_2 dx_2)^2}{x_3^2}.
\] (18.2)

The equation of the hypersurface gives
\[
x_3^2 = R^2 - x_1^2 - x_2^2.
\] (18.3)

Calling $x_1 = r'\cos(\theta), x_2 = r'\sin(\theta),$
\[
\text{d}x^2 = \frac{R^2 dr'^2}{R^2 - r'^2} + r'^2 d\theta^2.
\] (18.4)

It is natural to rescale $r' = r/R$. Then the metric takes the form, now for general $k$:
\[
\text{d}x^2 = \frac{dr'^2}{1 - kr'^2} + r'^2 d\theta^2.
\] (18.5)

Here $k = 1$ for a space of positive curvature; $k = -1$ for a space of negative curvature; $k = 0$ is a spacial case, corresponding to a flat universe.

We can immediately generalize this to three dimensions, allowing the radius, $R$, to be a function of time, $R \to a(t)$. In this way we obtain the Friedman–Robertson–Walker (FRW) metric:
\[
\text{d}s^2 = -dt^2 + a^2(t) \left\{ \frac{dr'^2}{1 - kr'^2} + r'^2 d\theta^2 + r'^2 \sin^2 \theta d\phi^2 \right\}.
\] (18.6)

By general coordinate transformations, this can be written in a number of other convenient and commonly used forms, which we will encounter in the following.

First, let’s evaluate the connection and the curvature. Again, the reader should evaluate a few of these terms by hand, and perform the complete calculation using one of the programs mentioned in the exercises in the previous chapter. The non-vanishing components of the connection are:
\[
\Gamma^i_{0j} = \frac{\dot{a}}{a} \delta^i_j \quad \Gamma^0_{ij} = g_{ij} \frac{\dot{a}}{a} \quad \Gamma^i_{jk} = \frac{g^{il}}{2} [g_{lj,k} + g_{lk,j} - g_{jk,l}]
\] (18.7)

and of the curvature are:
\[
\mathcal{R}_{00} = -3 \frac{\ddot{a}}{a}
\]
\[
\mathcal{R}_{ij} = g_{ij} \left[ \frac{\ddot{a}}{a} + 2H^2 - 2 \frac{k}{a^2} \right].
\] (18.8)

Here $H$ is known as the Hubble parameter,
\[
H = \frac{\dot{a}}{a},
\] (18.9)
and represents the expansion rate of the universe. Today

\[ H = 100 \, h \, \text{km s}^{-1} \, \text{Mpc}^{-1} \quad h = 0.73 \pm 0.03. \] 

(18.10)

The assumption of homogeneity and isotropy greatly restricts the form of the stress tensor; \( T_{\mu\nu} \) must take the \textit{perfect fluid} form:

\[ T_{00} = \rho \quad T_{ij} = p g_{ij} \] 

(18.11)

where \( \rho \) and \( p \) are the energy density and the pressure, and are assumed to be functions only of time. Then the \( 0-0 \) component of the Einstein equation gives the \textit{Friedmann equation}:

\[ \frac{\dot{a}^2}{a^2} + \frac{k}{a^2} = \frac{8\pi G}{3} \rho. \] 

(18.12)

The \( i-j \) components give:

\[ \frac{2\ddot{a}}{a} + \frac{\dot{a}^2}{a^2} + \frac{k}{a^2} = -8\pi G \rho. \] 

(18.13)

There is also an equation which follows from the conservation of the energy momentum tensor, \( T_{\mu\nu}^{\alpha\beta} = 0 \). This is

\[ d(\rho a^3) = -p d(a^3). \] 

(18.14)

This equation is familiar in thermodynamics as the equation of energy conservation, if we interpret \( a^3 \) as the volume. Suppose that we have the equation of state \( p = w \rho \), where \( w \) is a constant. Then Eq. (18.14) says:

\[ \rho \propto a^{-3(1+w)}. \] 

(18.15)

Three special cases are particularly interesting. For non-relativistic matter, the pressure is negligible compared to the energy density, so \( w = 0 \). For radiation (relativistic matter), \( w = 1/3 \). For a Lorentz-invariant stress tensor, \( T_{\mu\nu} = \Lambda g_{\mu\nu}, p = -\rho \), so \( w = -1 \). For these cases, it is worth remembering that

\begin{align*}
\text{Radiation:} & \quad \rho \propto R^{-4} \quad \text{Matter:} \quad \rho \propto R^{-3} ; \quad \text{Vacuum:} \quad \rho = \text{constant}. 
\end{align*} 

(18.16)

After taking account conservation of stress-energy and the Bianchi identities, only one of the two Einstein equations we have written is independent, and it is conventional to take the Friedmann equation. This equation can be rewritten in terms of the Hubble parameter,

\[ \frac{k}{H^2 a^2} = \frac{8\pi G \rho}{3H^2} - 1. \] 

(18.17)
Examining the right-hand side of this equation, it is natural to define a critical density,

$$\rho_c = \frac{3H^2}{8\pi G},$$

(18.18)

and to define $\Omega$ as the ratio of the density to the critical density,

$$\Omega = \frac{\rho}{\rho_c}.$$  

(18.19)

So $k = 1$ corresponds to $\Omega > 1$, $k = -1$ to $\Omega < 1$, and $k = 0$, a flat universe, to $\Omega = 1$. It is also natural to break up $\Omega$ into various components, such as radiation, matter, and cosmological constant. As we will discuss shortly, $\Omega$ today is equal to one within experimental errors; its main components are baryons, some unknown form of matter, and dark energy (perhaps cosmological constant),

$$\Omega_b = 0.04; \quad \Omega_{dm} = 0.28; \quad \Omega_{de} = 0.73.$$  

(18.20)

The present error bars are of order 4% on $\Omega_b$, and 13% on the dark matter density. The errors are similar on the dark energy determination.

The history of the universe divides into various eras, in which different forms of energy were dominant. The earliest era for which we have direct observational evidence is a period lasting from a few seconds after the big bang to about 100,000 years, during which the universe was radiation dominated. From the Friedmann equation, setting $k = 0$, we have that

$$a(t) = a(t_0)t^{1/2} \quad H = \frac{1}{2t}.$$  

(18.21)

For the period of matter domination, which began about $10^5$ years after the big bang and lasted almost to the present:

$$a(t) \propto t^{2/3} \quad H = \frac{2}{3t}.$$  

(18.22)

The universe appears today to be passing from an era of matter domination to a phase in which a (positive) cosmological constant dominates. Such a space is called a de Sitter space, and:

$$a(t) \propto e^{H_d t} \quad H_d = \frac{8\pi G}{3} \Lambda.$$  

(18.23)

In the radiation dominated and matter dominated periods, $H$ is, as we see from the formulas above, roughly a measure of the age of the universe. One can define the age of the universe more formally as:

$$t = \int \frac{a(t) \, da}{\dot{a}} = \int \frac{da}{aH}.$$  

(18.24)
The present value of the Hubble constant corresponds to \( t \approx 15 \) billion years. To obtain this correspondence between the age and the measured \( H_0 \), it is important to include both the matter and the cosmological constant pieces in the energy density. Note, in particular, that the integral is dominated by the most recent times, where \( H \) is smallest.

### 18.1 A history of the universe

As little as 50 years ago, most scientists would have been surprised at just how much we would eventually know about the universe: its present composition, its age, and its history, back to times a couple of minutes after the big bang. We have direct evidence of phenomena at much earlier times, though its full implications are difficult to interpret. We understand how galaxies formed and the abundance of the light elements. And we have a trove of plausible speculations, some of which we should be able to test over time.

In this section, we outline some of the basic features of this picture. Examining the FRW solution of Einstein’s equations, we see that the scale factor, \( a(t) \), gets monotonically smaller in the past. The Hubble parameter, \( H \), becomes larger. So at some time, the universe was much smaller than it is today. More precisely, the objects we see, or their predecessors, were far closer together. Far enough back in time, the material we currently see was highly compressed, and hot. So at some stage, the universe was likely dominated by radiation. Recall that, during a radiation-dominated era,

\[
a \sim t^{1/2} \quad H = \frac{1}{2t}.
\]

If we suppose that the universe remained radiation dominated as we look further back in time, we face a problem. At \( t = 0 \), the metric is singular – the curvature diverges. This is a finite time in the past, since

\[
\int_0^{\text{today}} dt \sqrt{-g_{00}}
\]

converges as \( t \to 0 \). This is not simply a feature of our particular assumptions about the equation of state or the precise form of the metric, but a feature of solution of Einstein’s equations; it is a consequence of singularity theorems due to Penrose and Hawking. The meaning of this singularity is a subject of much speculation. It might be smoothed out by quantum effects, or indicate something else. For now, we simply have to accept that some early time is inaccessible to us. To make progress, we suppose, first, that at time \( t_0 \), the universe was extremely hot, with temperature \( T_0 \), and reasonably homogeneous and isotropic. We then allow the universe to
Cosmology

evolve, using Einstein’s equations, the known particles and their interactions, and basic principles of statistical mechanics. As we will see, we can safely take $T_0$ at least as large as several MeV (corresponding to temperatures larger than $10^{10}$ K).

To make further progress, we need to think about the content of the universe and how it evolves as the universe expands. The universe cannot be precisely in thermal equilibrium, but for much of its history it is very nearly so, with matter and radiation evolving adiabatically. To understand why the expansion is adiabatic, note first that $H^{-1}$ is a time-scale for the expansion. If the universe is radiation dominated,

$$H \sim \frac{T^2}{M_p},$$

(18.27)

The rate for interactions in a gas will scale with $T$, multiplied, perhaps, by a few powers of coupling constants. For temperatures well below the Planck scale, the reaction rates will be much more rapid than the expansion rate. So at any given instant, the system will nearly be in equilibrium.

It is worth reviewing a few formulas from statistical mechanics. These formulas can be derived by elementary considerations, or by using the methods of finite-temperature field theory, as discussed in Appendix C. For a relativistic, weakly coupled Bose gas,

$$\rho = \frac{\pi^2}{30} g T^4 \quad p = \frac{\rho}{3},$$

(18.28)

while for a similar Fermi gas:

$$\rho = \frac{7}{8} \frac{\pi^2}{30} g T^4 \quad p = \frac{\rho}{3}.$$

(18.29)

Here $g$ is a degeneracy factor, counting the number of physical helicity states of each particle type. In the non-relativistic limit, for both bosons and fermions,

$$n = g \left( \frac{m T}{2\pi} \right)^{3/2} \exp\left(- (m - \mu)/T \right)$$

(18.30)

$$\rho = mn \quad p = nT \ll \rho.$$  

(18.31)

For temperatures well below $m$, the density rapidly goes to zero unless $\mu \neq 0$. Note that $\mu$ may be non-zero when there is a (possibly approximately) conserved quantum number. Perhaps the most notable example is baryon number.

We should pause here and discuss an aspect of general relativity which we have not considered up to now. A gravitational field alters the behavior of clocks. This is known as the gravitational red-shift. We can understand this in a variety of ways. First, if we have a particle at rest in a gravitational field, we see that the proper time is related to the coordinate time by a factor $\sqrt{g_{00}}$. Consider, alternatively,
the equation for a massless scalar field with momentum \( k \) in an expanding FRW universe. This is just \( D^\mu \partial_\mu \phi = 0 \). Using the non-vanishing Christoffel symbols, with \( \phi(\vec{x}, t) = e^{i\vec{k} \cdot \vec{x}} \phi(t) \),

\[
\dot{\phi}(k) + 3H\phi(k) + \frac{k^2}{a^2(t)} \phi = 0. \tag{18.32}
\]

As a result of the last term, the wavelength effectively decreases as \( 1/a(t) \). A photon red-shifts in precisely the same way.

The implications of this for the statistical mechanical distribution functions are interesting. Consider, first, a massless particle such as the photon. For such a particle, the distribution is:

\[
\int \frac{d^3k}{(2\pi)^3} \frac{1}{e^{k/T} - 1}. \tag{18.33}
\]

The effect of the red-shift is to maintain this form of the distribution, but to change the temperature, \( T(t) \propto 1/a(t) \). So even if the particles are not in equilibrium, they maintain an equilibrium distribution appropriate to the red-shifted temperature. This is not the case for massive particles.

Let’s imagine, then, starting the clock at temperatures well above the scale of QCD, but well below the scale of weak interactions, say at 10 GeV. In this regime, the density of \( W \)s and \( Z \)s is negligible, but the quarks and gluons behave as nearly free particles. So we can take an inventory of bosons and fermions light compared to \( T \). The bosons include the photon and the gluons; the fermions include all of the quarks and leptons except the top quark. So the effective \( g \), which we might call \( g_{10} \), is approximately 98. This means, for example, that

\[
\rho \approx \frac{g_{10} \pi^2}{30} T^4 \tag{18.34}
\]

and the Hubble constant is related to the temperature through:

\[
H = \left[ \frac{8\pi}{3} G \frac{\pi^2}{30} g_{10} T^4 \right]^{1/2}. \tag{18.35}
\]

This allows us to write a precise formula for the temperature as a function of time:

\[
T = \left[ \frac{16\pi}{3} G \frac{\pi^2}{30} g_{10} \right]^{-1/4} \left( \frac{1}{t} \right)^{1/2}. \tag{18.36}
\]

As the universe cools, QCD changes from a phase of nearly free quarks and gluons to a hadronic phase. At temperatures below \( m_\pi \), the only light species are the electron and the neutrinos. By this time, the anti-neutrons have annihilated with neutrons and the anti-protons against protons, leaving a small net baryon number,
the total number of neutrons and protons. There is, at this time, of order one baryon per billion photons. We will have much more to say about this slight excess later.

At this stage, interactions involving neutrinos maintain an equilibrium distribution of protons and neutrons. We can give a crude, but reasonably accurate, estimate of the temperature at which neutrino interactions drop out of equilibrium by asking when the interaction rate becomes comparable to the expansion rate. The cross section for neutrinos off of protons behaves as:

$$\sigma(\nu + p \rightarrow n + e) \approx G_F^2 E^2$$

and the number density of neutrinos is

$$n_\nu \approx \frac{\pi^2}{30} g_T T^3.$$  \(18.38\)

Combining this with our formula for the Hubble constant as a function of \(T\), Eq. (18.35), gives for the decoupling temperature, \(T_\nu\),

$$T_\nu^3 \approx G_F^{-2} M_p^{-1},$$  \(18.39\)

or

$$T_\nu \approx 2 \text{ MeV}.$$  \(18.40\)

This corresponds to a time of order 100 s after the big bang. At this point, neutron decays are not compensated by the inverse reaction. On the other hand, many neutrons will pair with protons to form stable light elements such as D and He. At about this time, the abundances of the various light elements are fixed.

There is a long history of careful, detailed calculations of the abundances of the light elements (H, He, D, Li, \(\cdots\)) which result from this period of decoupling. The abundances turn out to be a sensitive function of the ratio of baryon to photons, \(n_B/n_\gamma\). Astronomers have also made extensive efforts to measure this ratio. A comparison of observations and measurements, gives for the baryon to photon ratio:

$$\frac{n_B}{n_\gamma} = 6.1^{+0.3}_{-0.2} \times 10^{-10}.$$  \(18.41\)

We will see that this result receives strong corroboration from other sources.

The universe continues to cool in this radiation dominated phase for a long time. At \(t \approx 10^5\) years, the temperature drops to about 1 eV. At this time, electrons and nuclei can combine to form neutral atoms. As the density of ionized material drops, the universe becomes essentially transparent to photons. This is referred to as recombination. The photons now stream freely. As the universe continues to cool, the photons red-shift, maintaining a Planck spectrum. Today, these photons behave as if they had a temperature \(T \approx 3\) K. They constitute the cosmic microwave
background radiation (CMBR). This radiation was first observed in 1963 by Penzias and Wilson, and has since been extensively studied. It is very precisely a black body, with characteristic temperature 2.7 K. We will discuss other features of this radiation shortly.

It is interesting that, given the measured value of the matter density, matter and radiation have comparable energy densities at recombination time. At later times, matter dominates the energy density, and this continues to be the case to the present time.

In our brief history, another important event occurs at \( t \simeq 10^9 \) years. If we suppose that initially there were small inhomogeneities, these remain essentially frozen, as we will explain later, until the time of matter-radiation equality. They then grow with time. From observations of the CMBR, we know that these inhomogeneities were at the level of one part in \( 10^5 \). At about 1 billion years after the big bang, these then grow enough as to be non-linear, and their subsequent evolution is believed to give rise to the structure – galaxies, clusters of galaxies, and so on, that we see around us.

One surprising feature of the universe is that most of the energy density is in two forms which we cannot see directly. One is referred to as the “dark matter.” The possibility of dark matter was first noted by astronomers in the 1930s, from observations of rotation curves of galaxies. Simply using Newton’s laws, one can calculate the expected rotational velocities and one finds that these do not agree with the observed distribution of stars and dust in the galaxies. This is true for structures on many scales, not only galaxies but clusters and larger structures. Other features of the evolution of the universe are not in agreement with observation unless most of the energy density is in some other form. From a variety of measurements, \( \Omega_m \), the fraction of the critical energy density in matter, is known to be about 0.3. Nucleosynthesis and the CMBR give a much smaller fraction in baryons, \( \Omega_b \approx 0.05 \). In support of this picture, direct searches for hidden baryons are compatible with the smaller number, and have failed to find anything like the required density to give \( \Omega_m \).

Finally, it appears that we are now entering a new era in the history of the universe. For the last 14 billion years, the energy density has been dominated by non-relativistic matter. But at the present time, there is almost twice as much energy in some new form, with \( p < 0 \), referred to as dark energy. This is quite possibly a cosmological constant, \( \Lambda \). Current measurements are compatible with \( w = -1 \) \( (p = -\rho) \).

The picture we have described has extensive observational support. We have indicated some of this: the light element abundances and the observation of the CMBR. The agreement of these two quite different sets of observations for the baryon to photon ratio is extremely impressive. Observations of supernovae, the
age of the universe, and features of structure at different scales all support the existence of a cosmological constant (dark energy) constituting about 70% of the total energy.

This is not a book on cosmology, and the overview we have presented is admittedly sketchy. There are many aspects of this picture we have not discussed. Fortunately, there are many excellent books on the subject, some of which are mentioned as suggested reading.

**Suggested reading**

There are a number of good books and lectures on aspects of cosmology discussed here. Apart from the text of Weinberg (1972), mentioned earlier, these include the texts of Kolb and Turner (1990) and of Dodelson (2004).

**Exercises**

(1) Compute the Christoffel symbols and the curvature for the FRW metric. Verify the Friedmann equations.

(2) Verify Eq. (18.32).

(3) Consider the case of de Sitter space, $T_{\mu\nu} = -\Lambda g_{\mu\nu}$, with positive $\Lambda$. Show that the space expands exponentially rapidly. Compute the horizon – the largest distance from which light can travel to an observer.
In Chapter 18, we put forward a history of the universe. The picture is extremely simple. Its inputs are Einstein’s equations and the assumptions of homogeneity and isotropy. We also used our knowledge of laws of atomic, nuclear and particle physics. We saw a number of striking confirmations of this basic picture, but there are many puzzles.

(1) The most fundamental problem is that we don’t know the laws of physics relevant to temperatures greater than about 100 GeV. If there is only a single Higgs doublet at the weak scale, it is possible that we can extend this picture back to far earlier times. If there is, say, supersymmetry or large extra dimensions, the story could change drastically. Even if things are simple at the weak scale, we will not be able to extend the picture all the way back to $t = 0$. We have already seen that the classical gravity analysis breaks down.

(2) There are a number of features of the present picture we cannot account for within the Standard Model. Specifically, what is the dark matter? There is no candidate among the particles of the Standard Model. Is it some new kind of particle? As we will see, there are plausible candidates from the theoretical structures we have proposed, and they are the subject of intense experimental searches.

(3) The dark energy is very mysterious. Assuming it is a cosmological constant, it can be thought of as the vacuum energy of the underlying microphysical theory. As a number, it is totally bizarre. Its natural value should be set by the largest relevant scale, perhaps the Planck or unification scale, or the scale of supersymmetry breaking. Other proposals have been put forward to model the dark energy. One which has been extensively investigated is known as quintessence, the possibility that the energy is that of a slowly varying scalar field. Such models typically do not predict $w \neq -1$, and many are already ruled out by observations. But it should be stressed that these models are, if anything, less plausible than the possibility of a cosmological constant. First, one needs to explain why the underlying microphysical theory produces essentially zero cosmological constant, and a potential whose curvature is smaller than the present value of $H$. Then one needs to understand why the slowly varying field produces today the bizarre observed energy
density, without disturbing the successes of the cosmological picture for earlier times. It is probably fair to say that no convincing explanation of either aspect of the problem has been forthcoming.

(4) The value of the present baryon to photon ratio is puzzling:

\[ \frac{n_B}{n_\gamma} = (6.1^{+0.3}_{-0.2}) \times 10^{-10}. \]

As we will see, the question can alternately be phrased: why is this so small – or why is it so large? If the universe was always in thermal equilibrium, this number is a constant. So at very early times, there was a very tiny excess of particles over antiparticles. One might imagine that this is simply an initial condition, but, as A. Sakharov first pointed out, this is a number one might hope to explain through cosmology combined with microphysical theory. As we will discuss in detail later, it is necessary that the underlying microphysics violate baryon number and CP, and that there be a significant departure from thermal equilibrium. The Standard Model, as we have seen, violates both, and can generate a baryon number, but, as we will see, it is far too small. So modifications of the known physical laws are required to account for the observed density of baryons.

(5) Homogeneity, flatness and topological objects, such as monopoles, pose puzzles which suggest a phenomenon known as inflation. Consider, first, homogeneity. This certainly made the equations simple to solve, but it is puzzling. If we look at the cosmic microwave background, the temperature in different directions in the sky is equal to about a part in 10^5. But as we look out at distances 14 billion light years away, points separated by a tiny fraction of a degree were separated, at 100 000 years after the big bang, by an enormous distance compared to the horizon at that time. The problem is that the horizon decreases in size, as we look back, as \( \sqrt{t} \). So points separated by a degree were, at that time, separated by about 10^7 light years. But signals could not travel more than 10^5 light years by this time. So if these points had not been in causal contact by recombination, why should they have identical temperatures? For nucleosynthesis, which occurs much earlier, the question is even more dramatic.

(6) Flatness (\( \Omega_\text{tot} = 1 \)) may not seem puzzling at first, but let’s consider, again, the structure of the FRW metric. We have seen that the Friedmann equation can be recast as:

\[ \frac{8\pi G \rho}{H^2} = \Omega - 1. \]

Suppose, for example, that \( \Omega = 0.999 \) today. Then, at recombination, the left-hand side of this equation was more than 8 orders of magnitude smaller. So the energy density was equal to the critical density with extraordinary precision. This apparent fine tuning gets more and more extreme as we look further back in time.

(7) Monopoles: we have seen that simple grand unified theories predict the existence of magnetic monopoles. Their masses are typically of order the grand unification scale. So unless their density is many orders of magnitude (perhaps 14!) smaller than the density of baryons, their total energy density will be far greater than the observed energy density of the universe. Astrophysical limits turn out to be even smaller; passing through the
galaxy, monopoles would deplete the magnetic field. This sets a limit, known as the Parker bound, on the monopole flux in the galaxy:

\[ \mathcal{F} < 10^{-16} \left( \frac{M_{\text{mon}}}{10^{17} \text{ GeV}} \right) \text{cm}^{-2} \text{s}^{-1} \text{sr}^{-1}. \]  

(19.3)

On the other hand, we might expect, in a grand unified theory, quite extensive monopole production. We have seen that monopoles are topological objects. If there is a phase transition between a phase of broken and unbroken $SU(5)$, we would expect twists in the fields on scales of order the Hubble radius at this time, and a density of monopoles of order one per horizon volume. If the transition occurs at $T_0 = 10^{16}$ GeV, the Hubble radius is of order $T_0^2 / M_p$, so the density, in units of the photon density, $T_3$, is of order

\[ \frac{n_{\text{mon}}}{n_\gamma} = \frac{T_3}{M_p^3}. \]  

(19.4)

and can be larger than the baryon density.

In the following sections, we discuss these issues. We will study a possible solution to the homogeneity, flatness and monopole problems: inflation, the hypothesis that the universe underwent a period of extremely rapid expansion. We will see that there is some evidence that this phenomenon really occurred. Certainly there is nothing within the Standard Model itself which can give rise to inflation, so this points to the presence of some new phenomena, perhaps fields, perhaps more complicated entities, which are crucial to understanding the universe we see around us. We will describe some simple models of inflation, especially slow roll inflation, chaotic and hybrid inflation, and some of their successes and the puzzles which they raise. We will discuss inflationary theory’s biggest success: quantum mechanical fluctuations during inflation give rise to the perturbations which grow to become the structure we see around us in the universe. This introduction is not comprehensive, but should give the reader some tools to approach the vast literature which exists on this subject.

We next turn to the problem of the dark matter. We focus on two candidates: the lightest supersymmetric particle of the MSSM, and the axion. We explain how these particles might rather naturally be produced with the observed energy density, and discuss briefly the prospects for their direct detection. Then we turn to baryogenesis. We explain why the Standard Model has all of the ingredients to produce an excess of baryons over anti-baryons, but, given the value of the Higgs mass, this baryon number cannot be nearly as large as is observed. We then turn to baryon production in some of our proposals for physics beyond the Standard Model, focussing on three possibilities: heavy particle decay in grand unified theories, leptogenesis, and coherent production by scalar fields.
19.1 Inflation

The underlying idea behind inflation is that the universe behaved for a time as if (or nearly as if) the energy density was dominated by a positive cosmological constant, $\Lambda$. During this era, the Friedmann equation is that for de Sitter space,

$$H_i^2 = \left( \frac{\dot{a}}{a} \right)^2 = \frac{8\pi G}{3} \Lambda,$$

(19.5)

with solution

$$a(t) = e^{H_it}.$$  

(19.6)

If this situation holds for a time such that, say, $\Delta t H_i = 60$, then the universe expands by an enormous factor. Suppose, for example, $\Lambda = 10^{16}$ GeV; correspondingly $H_i \approx 10^{14}$ GeV. Then a patch of size $H^{-1}$ grows to be almost a centimeter in size. If, at the end of this period of inflation, the temperature of the universe is $10^{16}$ GeV, this patch would have grown, by the present time, by a factor of $10^{29}$. This is about the size of our present horizon!

One possibility for how this might come about is called “slow roll inflation.” Here one has a scalar field, $\phi$, with potential $V(\phi)$. $V(\phi)$, for some range of $\phi$, is slowly varying (Fig. 19.1). What we called $H_i$ is determined by the average value of the potential in the plateau region, $V_0$. If we assume that we have a patch, initially, of size a bit larger than $H_i^{-1}$, then we can write an equation of motion for the zero-momentum mode of the field, $\phi$, in this region:

$$g^{\mu\nu} D_\mu \partial_\nu \phi + V'(\phi) = 0.$$  

(19.7)

Because of our assumption of homogeneity (and isotropy), we can take the metric to have the Robertson–Walker form:

$$\ddot{\phi} + 3h \dot{\phi} + V'(\phi) = 0.$$  

(19.8)
We assume that the field is moving slowly, so that we can neglect the $\ddot{\varphi}$ term. Shortly, we will check whether this assumption is self-consistent. In this limit, the equation of motion is first order:

$$\ddot{\varphi} = -\frac{V'}{3H}. \quad (19.9)$$

We can integrate this equation to get $\Delta t$, the time it takes the field to traverse the plateau of the potential:

$$\Delta t = -\int d\varphi \frac{3H(\varphi)M_p^2}{V'(\varphi)}. \quad (19.10)$$

Assuming the validity of the slow roll approximation, the requirement for obtaining adequate inflation is:

$$N = \Delta t H > 60. \quad (19.11)$$

Now we can determine the conditions for the validity of the slow roll approximation. We simply want to check, from our solution, that $\ddot{\varphi} \ll 3H\dot{\varphi}, V'(\varphi)$. Differentiating the solution, leads to the conditions

$$\epsilon = \frac{1}{2} M_p^2 \left( \frac{V'}{V} \right)^2 \ll 1 \quad (19.12)$$

and

$$\eta = M_p^2 \frac{V''}{V}, \ |\eta| \ll 1. \quad (19.13)$$

How does inflation end? Near the minimum of the potential, we can approximate the potential as quadratic. So we might try to study an equation of the form:

$$\ddot{\varphi} + 3H \dot{\varphi} + m^2 \varphi = 0. \quad (19.14)$$

Were it not for the expansion, this equation would have a solution

$$\varphi = \varphi_0 \cos(mt). \quad (19.15)$$

In a quantum mechanical language, this would describe a coherent state of particles, with energy density

$$\rho = \frac{1}{2} m^2 \varphi_0^2. \quad (19.16)$$

These particles have zero momentum; the pressure, $T_{ij} = p\delta_{ij} = 0$. So, if this field dominates the energy density of the universe, we know that

$$a \sim t^{2/3}; \ H = \frac{2}{3} t. \quad (19.17)$$
In our toy model, we might imagine \( m \sim 10^{16} \text{ GeV} \gg H \), so we could solve the equation by assuming:

\[
\phi(t) = f(t) \cos(mt)
\]  

(19.18)

for a slowly varying function, \( f \). Plugging in, one finds

\[
f(t) = \frac{1}{t}.
\]  

(19.19)

Note that this means

\[
\rho = \rho_0 \left( \frac{t}{t_0} \right)^2 = \rho_0 \left( \frac{a}{a_0} \right)^3.
\]  

(19.20)

To summarize, we are describing a system which behaves like pressureless dust – zero-momentum particles – which is diluted by the expansion of the universe.

This description also gives us a clue as to the fate of the field, \( \phi \). Supposing that the \( \phi \) particles have a finite width, \( \Gamma \), they will decay in time \( 1/\Gamma \). We can include this in our equation of motion, writing:

\[
\ddot{\phi} + (3H + \Gamma) \dot{\phi} + V'(\phi) = 0.
\]  

(19.21)

When the particles decay, if their decay products include, for example, ordinary quarks, leptons and gauge fields, their interactions will bring them quickly to equilibrium. We can be at least somewhat quantitative about this. The condensate disappears at a time set by \( H \approx \Gamma \). If the universe quickly comes to equilibrium, the temperature must satisfy:

\[
\frac{\pi^2}{30} g T^4 = H^2 \frac{3}{8\pi G}.
\]  

(19.22)

At this temperature, we can estimate the rate of interaction. Since the typical particle energy will be of order \( T \), the cross sections will be of order

\[
\sigma = \frac{\alpha_i^2}{T^2}
\]  

(19.23)

We can multiply this by the density, \( n = (\pi^2/30) g^* T^3 \), to obtain a reaction rate. For inflation with the scales we are discussing, this is enormous compared to \( H \). The details by which equilibrium is established have been studied with some care. We can imagine that when a \( \phi \) first decays, it produces two very-high-energy particles. These will have rather small cross sections for scattering with other high-energy decay products, but these interactions degrade the energy, and the cross sections for subsequent interactions – and for interactions with previously produced particles – are larger. More careful study leads to a behavior with time where the temperature
rises to a maximum and then falls. This maximum temperature is:

\[ T_{\text{max}} \approx 0.8 g_*^{-1/4} m^{1/2} (\Gamma M_p)^{1/4}, \]  

(19.24)

where \( M \) is the mass of the inflaton.

### 19.1.1 Fluctuations: the formation of structure

One of the most exciting features of inflation is that it predicts that the universe is not exactly homogeneous and isotropic. We can’t do justice to this subject in this short section, but can at least give the flavor of the analysis and collect the crucial formulae. In order to have inflation, we need that the metric and fields are reasonably uniform over a region of size \( H_i^{-1} \). But because of quantum fluctuations, the fields, and in particular the scalar field, \( \phi \), cannot be completely uniform. We can estimate the size of these quantum fluctuations without great difficulty. In order that inflation occur at all, we need \( m_\phi \ll H \). So we will treat \( \phi \) as a massless free field in de Sitter space. For such a field, we can estimate the size of quantum fluctuations. As in flat space, we can expand the field, \( \phi \), in Fourier modes:

\[ \phi(\vec{x}, t) = \int \frac{d^3k}{(2\pi)^3} (e^{i\vec{k} \cdot \vec{x}} h(\vec{k}, t) + \text{c.c.}). \]  

(19.25)

The expansion coefficients, \( h \), obey the equation \( D_{\mu} \partial_{\nu} h(\vec{k}, t) e^{i\vec{k} \cdot \vec{x}} = 0 \), yielding, in the FRW background:

\[ \ddot{h} + 3H\dot{h} + \frac{k^2}{a^2} h = 0. \]  

(19.26)

Here \( k/a \) is the red-shifted momentum. In the case of de Sitter space, \( a \) grows exponentially rapidly. As soon as \( k/a \sim H \), the system becomes overdamped, and the value of \( h \) is essentially frozen. We will see this in a moment when we write an explicit solution of the equation.

It is convenient to change our choice of time variable. Rather than take the FRW form for the metric, we take a metric more symmetric between space and time:

\[ ds^2 = a^2(t)(-d\eta^2 + d\vec{x}^2). \]  

(19.27)

Here, in terms of our original variables,

\[ \frac{d\eta}{dt} = \pm \frac{1}{a}. \]  

(19.28)

So, choosing the + sign,

\[ \eta = \int \frac{da}{(\dot{a}/a)a^2} = \int \frac{da}{Ha^2}. \]  

(19.29)
In these coordinates, the equations of motion for $h(k, \eta)$ read:

$$\delta \ddot{\phi} + 2aH \delta \dot{\phi} + k^2 \delta \phi = 0.$$  \hspace{1cm} (19.31)

This equation is straightforward to solve. The solution can be written in terms of Bessel functions, but more transparently as:

$$\delta \phi_k = e^{-i k \eta} \sqrt{i k} \left[ 1 - i \frac{k \eta}{i k} \right].$$  \hspace{1cm} (19.32)

Note that for large times, $\eta \to 0$.

Further analysis is required to convert this expression into a fluctuation spectrum. The result is that the fluctuations in the energy density are roughly scale-invariant, and

$$\frac{\delta \rho}{\rho} \approx \left( \frac{H^2}{5 \pi \dot{\phi}} \right).$$  \hspace{1cm} (19.33)

Using the slow roll equation,

$$3H \dot{\phi} = V',$$  \hspace{1cm} (19.34)

gives

$$\frac{\delta \rho}{\rho} = \frac{3H^*}{5 \pi V'} = \frac{3V^{3/2}}{5 \pi V'M_p^3}.$$  \hspace{1cm} (19.35)

Much more detailed discussion of these formulas can be found in the suggested reading. These fluctuations quickly pass out of the horizon during inflation. While outside of the horizon, they are frozen. Subsequently, however, they reenter the horizon and begin to grow. Measurements of the CMBR indicate that

$$\frac{\delta \rho}{\rho} \sim 10^{-5}$$  \hspace{1cm} (19.36)

on horizon scales. Fluctuations which were within the horizon at the time of matter-radiation equality have grown linearly with time since that time. At about 1 billion years after the big bang, they became non-linear, and this appears to account adequately for the observed structure in the universe. Precise studies of the CMBR, the formation of structure, and Type Ia supernovas, as well as of the missing mass in structures on a wide range of scales, has allowed the determination of the composition of the universe.

But while the overall scenario is compelling, and has significant observational support, we lack a persuasive microphysical understanding of these phenomena.
19.1 Inflation

This is undoubtedly one of the great challenges of theoretical physics. In the next section, we describe two classes of models, each of which can be motivated by considerations of supersymmetry and of string theory, for inflation.

19.1.2 Models of inflation

There are almost as many models of inflation as there are physicists who have thought about the problem, and we cannot possibly sample all of them. In this section we survey a few. So far, we have discussed a model of a single scalar field. The properties of the potential for this field must be finely tuned in order to obtain enough \( e \)-foldings of inflation and small enough \( \delta \rho / \rho \). First, it is known from observations that the Hubble constant during inflation cannot be much larger than \( 10^{16} \) GeV. This means that the scalar mass cannot be comparable to the Planck mass, so we face the usual problem of light scalars. Second, the existence of a light scalar by itself does not insure adequate \( e \)-foldings and fluctuation spectrum without further fine tuning. The first models of slow roll inflation, based on what is known as the “Coleman–Weinberg” potential, were severely fine-tuned in both senses. We can illustrate the problems with another class of models, known as “chaotic inflation.” The idea is to consider a single scalar field, with a simple potential, such as \( \lambda \phi^4 \). This model can produce inflation if \( \lambda \) is very small, and the typical values of \( \phi \) are very large. The validity of the slow roll picture requires that \( \phi \gg M_p \). For definiteness, suppose \( \phi \approx 10M_p \). Then

\[
\frac{\delta \rho}{\rho} \approx \lambda^{1/2} \phi^2
\]

so that \( \lambda \sim 10^{-16} \). With this choice, one obtains, from Eq. (19.10), over 1000 \( e \)-foldings during inflation.

This model is very simple, but the extremely small value of the coupling is troubling, especially given the large value of \( \phi \). Not only is this small value of the coupling puzzling, but the \( \phi^n \) couplings, \( n > 4 \), expressed in Planck units, must be even smaller. Despite these concerns, this model has proven useful for considering many aspects of inflation, and it has been argued that some of its features may characterize a larger class of models.

Given that supersymmetry naturally produces light scalars, supersymmetry would seem a natural context in which to construct models of inflation. We have mentioned that in supersymmetric field theories and in string theory, one often encounters moduli, scalar fields whose potentials vanish in the some limit. Banks has suggested that for such fields, a potential of the form

\[
V = \mu^4 f(\phi/M_p)
\]
will often arise. Here $\mu$ is an energy scale determined by some dynamical phenomenon such as the scale of supersymmetry breaking. For such a potential, assuming that typical field values are of order $M_p$, we have from Eq. (19.35),

$$\frac{\delta \rho}{\rho} \approx \frac{\mu^2}{M_p^2},$$

(19.39)

From this, we have $\mu \approx 10^{15.5}$ GeV. The number of $e$-foldings is generically of order one; the potential must be tuned to the level of 1%, for example, if one is to obtain sufficient inflation. Still, this may seem less troubling than having many couplings less that $10^{-6}$. Note that $\mu$, the energy scale in a supersymmetric model of this kind with a single field is far larger than we have considered for low-energy supersymmetry breaking. Banks proposes that at the minimum of the potential, supersymmetry is unbroken, with vanishing $\langle W \rangle$ as a result of an $R$-symmetry.

Another class of models of some interest are known as hybrid models. These involve two fields. They are particularly interesting in the context of supersymmetry, where the scale of inflation can now be quite low, even comparable to the TeV scale. Here we consider an example from a class of models dubbed by Guth and Randall “supernatural,” since the presence of light scalars is again natural. The model contains two chiral fields, $\chi$ and $\phi$, responsible for inflation. Both $\chi$ and $\phi$, initially, sit far from their minima, in such a way that the field $\chi$ is very massive, but $\phi$ is light (more precisely, the curvature of the $\chi$ as potential is very large, but that of the $\phi$ potential is of order the basic scale of the model). During this period, $\chi$ is essentially frozen, while $\phi$ moves slowly towards a local minimum. The energy is dominated by the potential for $\chi$. As $\phi$ approaches its minimum, the $\chi$ field becomes lighter, and it eventually begins to roll towards its minimum. At this time, inflation ends. The universe reheats as $\chi$ oscillates about the minimum of the potential.

In more detail, we can take the superpotential to be

$$W = \frac{\lambda \chi \phi^3}{M}$$

(19.40)

and a soft breaking potential

$$V_{\text{soft}}(\phi, \chi) = m_{3/2}^2 g(\phi) + N m_{3/2}^2 f(\chi).$$

(19.41)

We assume that the global minimum of $g$ is at the origin, but that $f$ has a local minimum near $\chi = 0$, its global minimum being located a distance of order $M_p$ away.

The mass of the $\chi$ field receives a contribution from the superpotential term, which dominates until $\phi^2 \approx N m_{3/2} M_p$. When $\phi$ reaches this point, $\chi$ starts to move towards its true minimum. Unless the potential is further tuned, $\chi$ will reach its
minimum in a few Hubble times, ending inflation; $\chi$ oscillates about its minimum, leading to a period of matter domination, until it decays, reheating the universe.

The number of $e$-foldings, using Eq. (19.10), from large $\phi$ until $\phi$ reaches this critical value is of order $N$. The fluctuation amplitude is of order

$$\frac{\delta \rho}{\rho} \sim N \left( \frac{m_{3/2}}{M_p} \right)^{1/2} \approx N \times 10^{-7.5}. \quad (19.42)$$

So $N \sim 60$ gives a suitable number of $e$-foldings and a reasonable fluctuation spectrum. If the mass of $\chi$ is of order $N^{1/2}$ TeV, the $\chi$ width is of order:

$$\Gamma_\chi = \frac{m_\chi^3}{M_p^2} \propto N^{3/2}. \quad (19.43)$$

The corresponding reheating temperature, if $N \sim 60$ is of order $T_r = 10$ MeV. This is above nucleosynthesis, but just barely. It is compatible with everything we know. In such a picture, the thermal history of the universe began just before nucleosynthesis; there was not a phase transition in QCD or in the weak interactions, for example.

### 19.1.3 Constraints on reheating: the gravitino problem

Our discussion of supersymmetric models of inflation suggests a broad range of possible reheating temperatures, $T_r$. But there is a reason, at least in the context of supersymmetric theories, to think that there may be an upper bound on the reheating temperature. This is the problem of producing too many gravitinos. The gravitino lifetime is quite long,

$$\Gamma_{3/2} \approx \frac{m_{3/2}^3}{M_p^2}, \quad (19.44)$$

gravitinos might even be stable. As a minimal requirement, we need to suppose that the gravitinos did not dominate the energy density at the time of nucleosynthesis. If they did, again, they spoil the successful predictions of nucleosynthesis, but worse, as for moduli, their decay products destroy the light elements. Even though gravitinos are very weakly interacting, there is a danger that they will be overproduced during the period of reheating that follows inflation. A natural estimate for their production rate per unit volume is obtained by assuming that they are produced in two-body scattering, by light particles with densities of order $T^3$, and that their cross sections behave as $1/M_p^2$:

$$n^2 \langle \sigma v \rangle \approx T^6 \langle \sigma v \rangle \approx \frac{T^6}{M_p^2}. \quad (19.45)$$
Integrating this over a Hubble time, $M_p / T^2$, and dividing by the photon density, of order $T^3$ gives a rough estimate:

$$\frac{n_{3/2}}{s} \sim \frac{T}{M_p}.$$  \hfill (19.46)

Assuming 1 TeV for the gravitino mass, the requirement that gravitinos not dominate before nucleosynthesis gives $T < 10^{12}$ GeV. But this is too crude. Considering destruction of deuterium and lithium gives $T < 10^9$ GeV and possibly much smaller. This is a strong constraint on the nature of reheating after inflation. In the models suggested by Banks, for example, the reheating temperature can easily be larger. This is not a problem for the low-scale, hybrid models we discussed in the previous section.

19.2 The axion as dark matter

Within the set of ideas we have discussed for physics beyond the Standard Model, there are two promising candidates for dark matter. One is the axion, which we discussed in Chapter 5 as a possible solution to the strong CP problem. A second is the lightest supersymmetric particle in models with an unbroken $R$-parity. We first discuss the axion, mainly because the theory is particularly simple. To begin, we need to consider the astrophysics of the axion a bit further. There is a lower bound on the axion decay constant, or equivalently an upper bound on the axion mass, arising from processes in stars. Axions can be produced by collisions deep within the star. Then, because of their small cross section, most axions will escape, carrying off energy. This has the potential to disrupt the star. We can set a limit by requiring that the flux of energy from the stars not be more than a modest fraction of the total energy flux.

To estimate these effects, we can first ask what sorts of processes might be problematic. A pair of photons can collide and produce an axion (using the $aF\tilde{F}$ coupling of the axion to the photon). Axions can be produced from nuclei or electrons in Compton-like and Bremsstrahlung processes (Fig. 19.2). The typical energies will be of order $T$. 

![Fig. 19.2. In a Bremsstrahlung-like process, a lepton or nucleon can emit an axion when struck by a photon.](image-url)
For the Compton-like process of Fig. 19.2, the cross section is of order:

\[ \sigma_a \approx \frac{\alpha}{f_a^2}. \]  
(19.47)

The total rate per unit time for a given electron to scatter off a photon in this way will be proportional to the photon density, which we will simply approximate as \( T^3 \). To obtain the total emission per unit volume, we need to multiply, as well, by the electron density in the star. In the Sun, this number is of order the total number of protons or electrons, \( 1.16 \times 10^{57} \), divided by the cube of the solar radius (in particle physics units, \( 3.5 \times 10^{25} \text{ GeV}^{-1} \)). This corresponds to

\[ n_e \approx 3 \times 10^{-16} \text{ (GeV)}^3 \text{ electrons}. \]  
(19.48)

Rather than calculate the absolute rate, let’s compare with the rate for neutrino production. We would expect that if axions carry off far more energy than neutrinos, this is problematic. For neutrino production we might take \( n_e^2 \), and multiply by a typical weak cross section,

\[ \sigma_\nu = G_F^2 E^2. \]  
(19.49)

Finally, we take the temperature in the core of the star to be of order 1 MeV. Taking \( f_a = 10^9 \), gives, for the axion production rate:

\[ R_{\text{axion}} = 10^{-47} \text{ GeV}^{-4} \]  
(19.50)

while

\[ R_\nu = 10^{-47} \text{ GeV}^{-4}. \]  
(19.51)

Clearly this analysis is crude; much more care is required in enumerating different processes and evaluating their cross sections, and integrating over particle momentum distributions. But this rough calculation indicates that \( 10^9 \text{ GeV} \) is a plausible lower limit on the axion decay constant.

So we have a lower bound on the axion decay constant. An upper bound arises from cosmology. Suppose that the Peccei–Quinn symmetry breaks before inflation. Then throughout what will be the observable universe, the axion is essentially constant. But at early times, the axion potential is negligible. To be more precise, consider the equation of motion of the axion field:

\[ \ddot{a} + 3H \dot{a} + V'(a) = 0. \]  
(19.52)

At very early times, \( H \gg m \), and the system is overdamped. The axion simply doesn’t move. If the universe is very hot, the axion mass is actually much smaller than its current value. This is explained in Appendix C, but is easy to understand. At very high temperatures, the leading contribution in QCD to the axion potential
comes from instantons. Instanton corrections are suppressed by \( e^{-\frac{8\pi^2}{g^2(T)}} = (\Lambda / T)^{b_0} \). They are also suppressed by powers of the quark masses. In other words, they behave as:

\[
V(a) = \prod_f m_f \Lambda^{b_0} T^{-b_0 + n_f - 4} \cos(\theta)
\]

(19.53)

where \( \theta = a / f_a \), and \( n_f \) is the number of flavors with mass \( \ll T \). This goes very rapidly to zero at temperatures above the QCD scale.

So the value of the axion field – the \( \theta \)-angle – at early times, is most likely simply a random variable. Let’s consider, then, the subsequent evolution of the system. The equation of motion for such a scalar field in a FRW background is by now quite familiar:

\[
\ddot{a} + H \dot{a} + V'(a) = 0.
\]

(19.54)

\( V(a) \) also depends on \( T(t) \), which complicates slightly the solution, so let’s first just solve the problem with the zero-temperature axion potential. In this case, the axion will start to oscillate when \( H \sim m_a \). After this, the axions dilute like matter, i.e. as \( 1/a^3 \). The energy in radiation, on the other hand, dilutes like \( a^4 \propto T^{-4} \).

Assuming radiation domination when the axion starts to oscillate, we can determine the temperature at that time. Using our standard formula for the energy density,

\[
\rho = \frac{\pi^2}{30} g^* T^4
\]

(19.55)

we have, just above the QCD phase transition, \( g^* \approx 48 \) (with the gluons, three quark flavors, three light neutrinos and the photon). Just below, we don’t have the quarks or gluons, but we should include the pions, so \( g^* \approx 30 \). Taking the larger value

\[
T_a = 10^2 \text{ GeV} \left( \frac{10^{11} \text{GeV}}{f_a} \right)^{1/2}.
\]

(19.56)

At this time, the fraction of the energy density in axions is approximately

\[
\frac{\rho_{\text{axion}}}{\rho} = \frac{1}{2} \frac{f_a^2 m_a^2}{\rho} \approx \frac{1}{6} \frac{f_a^2}{M_p^2}.
\]

(19.57)

So if \( f_a = 10^{11} \) GeV, axions come to dominate the energy density quite late, at \( T \approx 10^{-3} \) eV. The temperature of axion domination scales with \( f_a \), so a \( 10^{16} \) GeV axion would dominate the energy density at 100 eV, which would be problematic.

However, the axion potential, as we have seen, is highly suppressed at temperatures above a few hundred MeV. So oscillation, in fact, sets in much later. We can make another crude estimate by simply supposing that the axion potential turns on at \( T = 100 \) TeV. In this case, the axion fraction is large, of order \( 1/g^* \). So if
19.3 The LSP as the dark matter

The axion density is to be compatible with the observed dark matter density, for any value of \( f_a \), we need to allow for the detailed temperature dependence of the axion mass. Using our formula for the axion potential as a function of temperature we can ask when the associated mass becomes of order the Hubble constant. After that time, axion oscillations are more rapid than the Hubble expansion, so we might expect that the axion density will damp, subsequently, like matter. Let’s take, specifically, \( f_a = 10^{11} \text{ GeV} \). For the axion mass, we can take:

\[
m_a(T) \approx 0.1 m_a(T = 0) \left( \frac{\Lambda_{QCD}}{T} \right)^{3.7}.
\]

The axion then starts to oscillate when \( T \approx 1.5 \text{ GeV} \). At this time, it represents about \( 10^{-9} \) of the energy density. One needs to do a bit more work to show that in the subsequent evolution, the energy in axions relative to the energy in radiation falls roughly as \( 1/T \), but for this decay constant, the axion and radiation energies become equal at roughly 1 eV. If the decay constant is significantly higher than \( 10^{11} \) GeV, then the axions start to oscillate too late, and dominate the energy density too early. If the decay constant is significantly smaller, then the axions cannot constitute the presently observed dark matter.

So it is remarkable that there is a rather narrow range of axion decay constants consistent with observation. On the other hand, some of the assumptions we have made in this section are open to question. In the case of hybrid inflation we have seen that the universe might never have been much hotter than 10 MeV. In this case, the upper limit on the axion decay constant, as we will discuss further later, can be much weaker.

19.3 The LSP as the dark matter

A stable particle is not necessarily a good dark matter candidate. But we can make a crude calculation which indicates that the LSP density is in a suitable range to be the dark matter. Consider particles, \( X \), with mass of order 100 GeV interacting with weak interaction strength. Their annihilation and production cross sections go as \( G_\phi^2 E^2 \). So, in the early universe, the corresponding interaction rate is of order

\[
\Gamma \approx \rho_X G_\phi^2 E^2 \approx \rho_X G_\phi^2 T^2.
\]

These interactions will drop out of equilibrium when the mass of the particle \( X \) is small compared to the temperature, so that there is a large Boltzmann suppression of their production. This will occur when this rate is of order the expansion rate, or

\[
T^3 e^{-M_X/T} \langle v \sigma \rangle \sim \frac{T^2}{M_p}.
\]

Since the exponent is very small, once \( T \sim 10M_X \), we can get a rough estimate of the density by saying that:

\[
e^{-M_X/T} T^3 \sim G_F^{-2} / M_p.
\] (19.61)

The ratio, \( n_X / s \), then, is of order

\[
n_X / s \approx G_F^{-2} / (M_p T^3).
\] (19.62)

Assuming that \( M_X \sim 100 \text{ GeV} \), and \( T \sim 10 \text{ GeV} \), this gives about \( 10^{-9} \) for the right-hand side. Since the energy density in radiation damps like \( T^{-4} \), while that for matter damps like \( T^{-3} \), this gives matter-radiation equality at temperatures of order an electronvolt, as in the standard big bang cosmology.

Needless to say, this calculation is quite crude. Extensive, far more sophisticated, calculations have been done to find the regions of parameter space in different supersymmetric models which are compatible with the observed dark matter density. The basic starting point for these analyses is the Boltzmann equation. If the basic process is of the form \( 1 + 2 \leftrightarrow 3 + 4 \), then:

\[
a^{-3} \frac{d}{dt} (n_1 a^3) = \int \frac{d^3 p_1}{(2\pi)^3 2E_1} \int \frac{d^3 p_2}{(2\pi)^3 2E_2} \int \frac{d^3 p_3}{(2\pi)^3 2E_3} \int \frac{d^3 p_4}{(2\pi)^3 2E_4} (f_3 f_4[1 \pm f_1][1 \pm f_2] - f_1 f_2[1 \pm f_3][1 \pm f_4])(2\pi)^4 \delta^4(p_1 + p_2 - p_3 - p_4)|\mathcal{M}|^2.
\] (19.63)

The functions \( f_1, \ldots, f_4 \) are the distribution functions for the different species. These equations can be simplified in the high-temperature limit using Boltzmann statistics:

\[
f(E) \rightarrow e^{\mu/T} e^{-E/T}.
\] (19.64)

Interactions are still fast enough at this time to maintain equilibrium of the \( X \) momentum distributions (kinetic equilibrium) but not that of \( X \) number. So it is the limiting value of the \( X \) chemical potential, \( \mu_X \), which we seek. In this limit, we have:

\[
f_3 f_4[1 \pm f_1][1 \pm f_2] - f_1 f_2[1 \pm f_3][1 \pm f_4] \rightarrow e^{-(E_1 + E_2)/T} \left( e^{(\mu_1 + \mu_2)/T} - e^{(\mu_3 + \mu_4)/T} \right).
\] (19.65)

Here we have used \( E_1 + E_2 = E_3 + E_4 \).

Things simplify further as all but the \( X \) particle (particle 1) are light, and nearly in equilibrium. Defining \( n_i^{(0)} \) as the distributions in the absence of a chemical potential, and defining the thermally averaged cross section:

\[
\langle \sigma v \rangle = \frac{1}{n_1^{(0)} n_2^{(0)}} \int \frac{d^3 p_1}{(2\pi)^3 2E_1} \int \frac{d^3 p_2}{(2\pi)^3 2E_2} \int \frac{d^3 p_3}{(2\pi)^3 2E_3} \int \frac{d^3 p_4}{(2\pi)^3 2E_4} |\mathcal{M}|^2,
\] (19.66)
we have

\[ a^{-3} \frac{d(n_a a^3)}{dt} = n_X n_2 \langle \sigma v \rangle \left( 1 - \frac{n_X}{n_X^{(0)}} \right). \] (19.67)

Detailed solutions of these equations (often without some of these simplifications) reveal, as one would expect, a range of parameters in the MSSM compatible with the observed dark matter density (Fig 19.3).

So while it is disturbing that we need to impose additional symmetries in the MSSM in order to avoid proton decay, it is also exciting that this leads to a possible solution of one of the most critical problems of cosmology: the identity of the dark matter.

### 19.4 The moduli problem

We have seen that, in supersymmetric theories, there are frequently light moduli. In string models, we will find that such fields are ubiquitous. Such moduli, if they exist, pose a cosmological problem with some resemblance to the problems of axion cosmology.

In this section, we will formulate the problem as it arises in gravity-mediated supersymmetry breaking. The potential for the modulus, \( \phi \), would be expected to take the form:

\[ V(\phi) = m_{3/2}^2 M_p^2 f(\phi / M_p). \] (19.68)
By assumption, $f$ has a minimum at some value, $\phi$, of order $M_p$. In the early universe, when the Hubble parameter is much greater than $m_{3/2}$, this potential is effectively quite small, and there is in general no obvious reason that the field should sit at its minimum. So, when $H \sim m_{3/2}$, the field is likely to lie at a distance $M_p$, in field space from the minimum, and store an energy of order $m_{3/2}^2 M_p^2$. Like the axion, after this time, assuming it is within the domain of attraction of the minimum, it will oscillate, behaving like pressureless dust. Almost immediately, given our assumptions about scales, it comes to dominate the energy density of the universe, and it continues to do so until it decays. The problem is that the decay occurs quite late, and the temperature after the decay is likely to be quite low.

We can estimate the temperature after $\phi$ decay, $T_r$, by considering first the lifetime of the $\phi$ particle. We might expect this to be:

$$\Gamma_\phi = \frac{m_{3/2}^3}{M_p^2}$$

assuming that the couplings of the $\phi$ field to other light fields are suppressed by a single power of $M$. Assuming that the decay products quickly thermalize, and noting that $\Gamma_\phi$ is the Hubble constant at the time of $\phi$ decay, gives

$$T_r^4 \approx \frac{m_{3/2}^6}{M_2^4} \approx (10 \text{ keV})^4.$$  

(19.70)

Here we are assuming $m_{3/2} \approx 1 \text{ TeV}$. This is a temperature well below nucleosynthesis temperature. So in such a picture, the universe is matter dominated during nucleosynthesis. But the situation is actually far worse: the decay products almost certainly destroy deuterium and the other light nuclei.

Two plausible resolutions for this puzzle have been put forward (apart from the obvious one that perhaps there is no supersymmetry or no moduli): the moduli might be significantly more massive than $1 \text{ TeV}$. Note that $T_r$ scales like the moduli masses to the $3/2$ power, so if the moduli masses are of order hundreds of TeV, this temperature can be sufficiently high that nucleosynthesis occurs (again). There is, potentially, a serious problem with such a picture. During the $\phi$ decay, significant entropy is produced. For example, if the temperature of the universe when the moduli came to dominate was $\sqrt{m_{3/2} M_p}$, when the moduli decay it is far smaller than $T_r$. Correspondingly, the entropy is increased by a factor which can easily be $10^9$–$10^{12}$. Any baryon number produced before these decays is diluted by a corresponding factor. One can hope that the baryons are produced in the decays of these moduli, but this requires one understand why such low-energy baryon-number violation doesn’t cause difficulties for proton decay. In the next section, we will discuss possible mechanisms to produce the baryon asymmetry, and we will see
that there is one which is capable of producing a large enough asymmetry to survive moduli decays.

19.5 Baryogenesis

The baryon to photon ratio, $n_B/n_\gamma$, is quite small. At early times, when QCD was nearly a free theory, this slight excess would have been extremely unimportant. But for the structure of our present universe, it is terribly important. One might imagine that $n_B/n_\gamma$ is simply an initial condition, but it would be more satisfying if we could have some microphysical understanding of this asymmetry between matter and antimatter. Andrei Sakharov, after the experimental discovery of CP violation, was the first to state precisely the conditions under which the laws of physics could lead to a prediction for the asymmetry.

(1) *The underlying laws must violate baryon number.* This one is obvious; if there is, for example, no net baryon number initially, and if baryon number is not conserved, the baryon number will always be zero.

(2) *The laws of nature must violate CP.* Otherwise, for every particle produced in interactions, an antiparticle will be produced as well.

(3) *The universe, in its history, must have experienced a departure from thermal equilibrium.* Otherwise, the CPT theorem insures that the numbers of baryons and anti-baryons at equilibrium are zero. This can be proven with various levels of rigor, but one way to understand this is to observe that CPT insures that the masses of the baryons and anti-baryons are identical, so at equilibrium their distributions should be the same.

Subsequently, there have been many proposals for how the asymmetry might arise. In the next sections, we will describe several. *Leptogenesis* relies on lepton-number violation, something we know is true of nature, but of whose underlying microphysics we are ignorant. *Baryogenesis through coherent scalar fields* (Affleck–Dine baryogenesis) also seems plausible. It is only operative if supersymmetry is unbroken to comparatively low energies, but it can operate quite late in the evolution of the universe and can be extremely efficient. This could be important in situations like moduli decay or hybrid inflation where the entropy of the universe is produced very late, after the baryon number.

19.5.1 Baryogenesis through heavy particle decays

One well-motivated framework in which to consider baryogenesis is grand unification. Here one can satisfy all of the requirements for baryogenesis. Baryon-number violation is one of the hallmarks of GUTs, and these models possess various sources of CP violation. As far as departure from equilibrium, the massive gauge bosons,
X, provide good candidates for a mechanism. To understand in a bit more detail how the asymmetry can come about, note that CPT requires that the total decay rate of X is the same as that of its antiparticle $\bar{X}$. But it does not require equality of the decays to particular final states (partial widths). So starting with equal numbers of X and $\bar{X}$ particles, there can be a slight asymmetry between processes such as

$$X \rightarrow dL; \ X \rightarrow \bar{Q}\bar{u}$$ \hspace{1cm} (19.71)

and

$$\bar{X} \rightarrow \bar{d}\bar{L}; \ \bar{X} \rightarrow Qu.$$ \hspace{1cm} (19.72)

The tree graphs for these processes are necessarily equal; any CP-violating phase simply cancels out when we take the absolute square of the amplitude (see Fig. 19.4). This is not true in higher order, where additional phases associated with real intermediate states can appear. Actually computing the baryon asymmetry requires an analysis of the Boltzmann equations, of the kind we have encountered in our discussion of dark matter.

There are reasons to believe, however, that GUT baryogenesis is not the origin of the observed baryon asymmetry. Perhaps the most compelling of these has to do with inflation. Assuming that there was a period of inflation, any pre-existing baryon number was greatly diluted. So in order that one produces baryons through X boson decay, it is necessary that the reheating temperature after inflation be at least comparable to the X boson mass. But as we have explained, a reheating temperature greater than $10^9$ GeV leads to cosmological difficulties, especially overproduction of gravitinos.

### 19.5.2 Electroweak baryogenesis

The Standard Model, for some range of parameters, can satisfy all of the conditions for baryogenesis. We have seen in our discussion of instantons that the Standard Model violates baryon number. This violation, we saw, is extremely small at low temperatures, so small that it is unlikely that a single baryon has decayed in the history of the universe this way. The rate is so small because baryon-number violation
is a tunneling process. If one could excite the system to high energies, one might expect that the rate would be enhanced. At high enough energies, the system might simply be above the barrier. One can find the configuration which corresponds to sitting on top of the barrier by looking for static, unstable solutions of the equations of motion. Such a solution is known. It is called a sphaleron (from Greek, meaning “ready to fall”). The barrier is quite high – from familiar scaling arguments, the sphaleron energy is of order $E_{sp} = 1/\alpha M_W$. But this configuration is large compared to its energy; it has size of order $M_W$. As a result, it is difficult to produce in high-energy scattering. Two particles with enough energy to produce the sphaleron have momenta much higher than $M_W$. As a result, their overlap with the sphaleron configuration is exponentially suppressed.

At high temperatures one might expect that the sphaleron rate would be controlled by a Boltzmann factor, $e^{-E_{sp}/T}$. So as the temperature increases, the rate would grow significantly. This turns out to be the case. In fact, the rate is even larger than one might expect from this estimate, because $E_{sp}$ itself is a function of $T$. At very high temperatures, the rate has no exponential suppression at all, and behaves as:

$$\Gamma = (\alpha_w T)^4.$$  \hfill (19.73)

These phenomena are discussed in Appendix C.

If the Higgs mass is not too large, the Standard Model can produce a significant departure from equilibrium. As one raises the temperature, a simple calculation, described in Appendix C, shows that the Higgs mass increases (the mass-squared becomes less negative) with temperature. At very high temperature, the $SU(2) \times U(1)$ symmetry is restored. The phase transition between these two phases, for a sufficiently light Higgs, is first order. It proceeds by the formation of bubbles of the unbroken phase. The surfaces of these bubbles can be sites for baryon number production. These phenomena are also discussed in Appendix C. So the third of Sakharov’s conditions can be satisfied.

Finally, we know that the Standard Model violates CP. We also know, however, that it is crucial that there are three generations, and that this CP violation vanishes if any of the quark masses are zero. As a result, even if the Higgs mass is small enough that the transition is strongly first order, any baryon number produced is suppressed by several powers of Yukawa couplings, and is far too small to account for the observed matter–antimatter asymmetry.

In the MSSM, the situation is somewhat better. There is a larger region of the parameter space in which the transition is first order, and as we have seen, there are many new sources of CP violation. As a result, there is, as of this writing, a small range of parameters where the observed asymmetry could be produced in this way.
Leptogenesis

There is compelling evidence that neutrinos have mass. The most economical explanation of these masses is that they arise from a seesaw, involving gauge singlet fermions, $N_a$. These couplings violate lepton number. So according to Sakharov’s principles, we might hope to produce a lepton asymmetry in their decays. Because the electroweak interactions violate baryon and lepton number at high temperatures, the production of a lepton number leads to the production of baryon number.

In general, there may be several $N_a$ fields, with couplings of the form:

$$\mathcal{L}_N = M_{ab} N_a N_b + h_{ai} H L_i N_a + \text{c.c.}$$

(19.74)

In a model with three $N$s, there are CP-violating phases in the Yukawa couplings of the $N$s to the light Higgs. The heaviest of the right-handed neutrinos, say $N_1$, can decay to $\ell$ and a Higgs, or to $\bar{\ell}$ and a Higgs. At tree level, as in the case of GUT baryogenesis, the rates for production of leptons and anti-leptons are equal, even though there are CP-violating phases in the couplings. It is necessary, again, to look at quantum corrections, in which dynamical phases can appear in the amplitudes. At one loop, the decay amplitude for $N$ has a discontinuity associated with the fact that the intermediate $N_1$ and $N_2$ can be on shell (similar to Fig. 19.4). So one obtains an asymmetry proportional to the imaginary parts of the Yukawa couplings of the $N$s to the Higgs:

$$\epsilon = \frac{\Gamma(N_1 \to \ell H_2) - \Gamma(N_1 \to \bar{\ell} H_2)}{\Gamma(N_1 \to \ell H_2) + \Gamma(N_1 \to \bar{\ell} H_2)} = \frac{1}{8\pi} \frac{1}{h h^\dagger} \sum_{i=2,3} \text{Im}[(h_v h_v^\dagger)_{1i}]^2 f \left( \frac{M_i^2}{M_1^2} \right),$$

(19.75)

where $f$ is a function that represents radiative corrections. For example, in the Standard Model $f = \sqrt{x}[(x - 2)/(x - 1) + (x + 1) \ln(1 + 1/x)]$, while in the MSSM $f = \sqrt{x}[2/(x - 1) + \ln(1 + 1/x)]$. Here we have allowed for the possibility of multiple Higgs fields, with $H_2$ coupling to the leptons. The rough order of magnitude here is readily understood by simply counting loops factors. It need not be terribly small.

Now, as the universe cools through temperatures of order of masses of the $N$s, they drop out of equilibrium, and their decays can lead to an excess of neutrinos over antineutrinos. Detailed predictions can be obtained by integrating a suitable set of Boltzmann equations. But a rough estimate can be obtained by noting that the $N_a$s drop out of equilibrium when their production rate becomes comparable to the expansion rate of the universe. If $\alpha$ represents a typical coupling, this occurs roughly when

$$\pi \alpha^2 T e^{-M_N/T} \approx \frac{T^2}{M_p}.$$  

(19.76)
19.5 Baryogenesis

Assuming that in the polynomial terms, \( T \sim M_N/10 \), gives that the density at this time is of order

\[
\frac{\rho_N}{\rho_{\text{tot}}} \sim \frac{\pi T}{M_p \alpha^2}.
\]  

(19.77)

Multiplying by \( \epsilon \), the average asymmetry in \( N \) decays, this estimate suggests a lepton number – and hence a baryon number – of order:

\[
\frac{\rho_B}{\rho_{\text{tot}}} \approx \epsilon \frac{M_N}{10\pi \alpha^2 M_p}.
\]  

(19.78)

We have seen that \( \epsilon \) is suppressed by a loop factor and by Yukawa couplings. So this number can easily be compatible with observations, or even somewhat larger, depending on a variety of unknown parameters.

These decays, then, produce a net lepton number, but not baryon number (and hence a net \( B - L \)). The resulting lepton number will be further processed by sphaleron interactions, yielding a net lepton and baryon number (recall that sphaleron interactions preserve \( B - L \), but violate \( B \) and \( L \) separately). One can determine the resulting asymmetry by an elementary thermodynamics exercise. One introduces chemical potentials for each neutrino, quark and charged lepton species. One then considers the various interactions between the species at equilibrium. For any allowed chemical reaction, the sum of the chemical potentials on each side of the reaction must be equal. For neutrinos, the relations come from:

1. the sphaleron interactions themselves
   \[
   \sum_i (3\mu_{\ell_i} + \mu_{\nu_i}) = 0;
   \]  
   (19.79)

2. a similar relation for QCD sphalerons
   \[
   \sum_i (2\mu_{\nu_i} - \mu_{u_i} - \mu_{d_i}) = 0;
   \]  
   (19.80)

3. vanishing of the total hypercharge of the universe
   \[
   \sum_i (\mu_{\ell_i} - 2\mu_{\bar{u}_i} + \mu_{\bar{d}_i} - \mu_{\nu_i} + \mu_{\bar{\nu}_i}) + \frac{2}{N} \mu_H = 0;
   \]  
   (19.81)

4. the quark and lepton Yukawa couplings give relations
   \[
   \mu_{\nu_i} - \mu_{\phi} - \mu_{d_j} = 0, \quad \mu_{\nu_i} - \mu_{\phi} - \mu_{u_j} = 0, \quad \mu_{\ell_i} - \mu_{\phi} - \mu_{e_j} = 0.
   \]  
   (19.82)

The number of equations here is the same as the number of unknowns. Combining these, one can solve for the chemical potentials in terms of the lepton chemical potential, and finally in terms of the initial \( B - L \). With \( N \) generations,

\[
B = \frac{8N + 4}{22N + 13} (B - L).
\]  

(19.83)
Reasonable values of the neutrino parameters give asymmetries of the order we seek to explain. Note sources of small numbers.

1. The phases in the couplings.
2. The loop factor.
3. The small density of the $N$ particles when they drop out of equilibrium. Parametrically, one has, e.g., for production,

\[ \Gamma \sim e^{-M/T} g^2 T \]  

which is much less than $H \sim T^2/M_p$ once the density is suppressed by $T/M_p$, i.e. of order $10^{-6}$ for a $10^{13}$ GeV particle.

It is interesting to ask: assuming that these processes are the source of the observed asymmetry, how many parameters which enter into the computation can be measured? It is likely that, over time, many of the parameters of the light neutrino mass matrices, including possible CP-violating phases, will be measured. But while these measurements determine some of the $N_i$ couplings and masses, they are not, in general, enough. In order to give a precise calculation, analogous to the calculations of nucleosynthesis, of the baryon number density, one needs additional information about the masses of the fields $N_i$. One either requires some other (currently unforeseen) experimental access to this higher-scale physics, or a compelling theory of neutrino mass in which symmetries, perhaps, reduce the number of parameters.

### 19.5.4 Baryogenesis through coherent scalar fields

In supersymmetric theories, the ordinary quarks and leptons are accompanied by scalar fields. These scalar fields carry baryon and lepton number. A coherent field, i.e. a large classical value of such a field, can in principle carry a large amount of baryon number. As we will see, it is quite plausible that such fields were excited in the early universe, and this can lead to a baryon asymmetry.

To understand the basics of the mechanism, consider first a model with a single complex scalar field. Take the Lagrangian to be

\[ \mathcal{L} = \left| \partial_\mu \phi \right|^2 - m^2 |\phi|^2. \]  

This Lagrangian has a symmetry, $\phi \rightarrow e^{i\alpha} \phi$, and a corresponding conserved current, which we will refer to as baryon number:

\[ j_\mu^B = i(\phi^* \partial_\mu \phi - \phi \partial_\mu \phi^*). \]  

It also possesses a “CP” symmetry:

\[ \phi \leftrightarrow \phi^*. \]  

With supersymmetry in mind, we will think of $m$ as of order $M_W$. 

If we focus on the behavior of spatially constant fields, \( \phi(\mathbf{x}, t) = \phi(t) \), this system is equivalent to an isotropic harmonic oscillator in two dimensions. In field theory, however, we expect that higher-dimension terms will break the symmetry. In the isotropic oscillator analogy, this corresponds to anharmonic terms which break the rotational invariance. With a general initial condition, the system will develop some non-zero angular momentum. If the motion is damped, so that the amplitude of the oscillations decreases, these rotationally non-invariant terms will become less important with time.

In the supersymmetric field theories of interest, supersymmetry will be broken by small quartic and higher-order couplings, as well as by soft masses for the scalars. So as a simple model, take:

\[
\mathcal{L}_I = \lambda |\phi|^4 + \epsilon \phi^3 \phi^* + \sigma \phi^4 + \text{c.c.} \tag{19.88}
\]

These interactions clearly violate “B.” For general complex \( \epsilon \) and \( \sigma \), they also violate CP. As we will shortly see, once supersymmetry is broken, quartic and higher-order couplings can be generated, but these couplings \( \lambda, \epsilon, \sigma \ldots \) will be extremely small, \( \mathcal{O}(m_{3/2}^2/M_p^2) \) or \( \mathcal{O}(m_{3/2}^2/M_{\text{GUT}}^2) \).

In order that these tiny couplings lead to an appreciable baryon number, it is necessary that the fields, at some stage, were very large. To see how the cosmic evolution of this system can lead to a non-zero baryon number, first note that at very early times, when the Hubble constant, \( H \gg m \), the mass of the field is irrelevant. It is thus reasonable to suppose that at this early time \( \phi = \phi_0 \gg 0 \); later we will describe some specific suggestions as to how this might come about. This system then evolves like the axion or moduli. In the the radiation and matter dominated eras, respectively, one has that

\[
\phi = \frac{\phi_0}{(mt)^{3/2}} \sin(mt) \quad \text{(radiation)} \tag{19.89}
\]

\[
= \frac{\phi_0}{mt} \sin(mt) \quad \text{(matter).} \tag{19.90}
\]

In either case, the energy behaves, in terms of the scale factor, \( R(t) \), as

\[
E \approx m^2 \phi_0^3 \left( \frac{R_0}{R} \right)^3, \tag{19.91}
\]

i.e. it decreases like \( R^3 \), as would the energy of pressureless dust. One can think of this oscillating field as a coherent state of \( \phi \) particles with \( \mathbf{p} = 0 \).

Now let’s consider the effects of the quartic couplings. Since the field amplitude damps with time, their significance will decrease with time. Suppose, initially, that \( \phi = \phi_0 \) is real. Then the imaginary part of \( \phi \) satisfies, in the approximation that \( \epsilon \) and \( \delta \) are small,

\[
\ddot{\phi}_i + 3H \dot{\phi}_i + m^2 \phi_i \approx \text{Im}(\epsilon + \delta) \phi_i^3. \tag{19.92}
\]
For large times, the right-hand side falls as \( t^{-9/2} \), whereas the left-hand side falls off only as \( t^{-3/2} \). As a result, just as in our mechanical analogy, baryon number (angular momentum) violation becomes negligible. The equation goes over to the free equation, with a solution of the form

\[
\phi_i = a_r \frac{\text{Im}(\epsilon + \delta)\phi_0^3}{m^2(mt)^{3/4}} \sin(mt + \delta_r) \quad \text{(radiation),} \tag{19.93}
\]

\[
\phi_i = a_m \frac{\text{Im}(\epsilon + \delta)\phi_0^3}{m^3t} \sin(mt + \delta_m) \quad \text{(matter),} \tag{19.94}
\]

in the radiation and matter dominated cases, respectively. The constants \( \delta_m, \delta_r, a_m \) and \( a_r \) can easily be obtained numerically, and are of order unity:

\[
a_r = 0.85 \quad a_m = 0.85 \quad \delta_r = -0.91 \quad \delta_m = 1.54. \tag{19.95}
\]

But now we have a non-zero baryon number; substituting in the expression for the current,

\[
n_B = 2a_r \text{Im}(\epsilon + \delta)\frac{\phi_0^2}{m(mt)^2} \sin(\delta_r + \pi/8) \quad \text{(radiation)} \tag{19.96}
\]

\[
n_B = 2a_m \text{Im}(\epsilon + \delta)\frac{\phi_0^2}{m(mt)^2} \sin(\delta_m) \quad \text{(matter).} \tag{19.97}
\]

Note that CP violation here can be provided by phases in the couplings and/or the initial fields. Note also as expected, \( n_B \) is conserved at late times, in the sense that the baryon number per comoving volume is constant.

This mechanism for generating baryon number could be considered without supersymmetry. In that case, it begs several questions.

- What are the scalar fields carrying baryon number?
- Why are the \( \phi^4 \) terms so small?
- How are the scalars in the condensate converted to more familiar particles?

In the context of supersymmetry, there is a natural answer to each of these questions. First, as we have stressed, there are scalar fields carrying baryon and lepton number. As we will see, in the limit that supersymmetry is unbroken, there are typically directions in the field space in which the quartic terms in the potential vanish. Finally, the scalar quarks and leptons will be able to decay (in a baryon- and lepton-number conserving fashion) to ordinary quarks.

### 19.6 Flat directions and baryogenesis

To discuss the problem of baryon number generation, we first want to examine the theory in a limit in which we ignore the soft SUSY-breaking terms. After all,
at very early times, $H \gg M_W$, and these terms are irrelevant. We are now quite familiar with the fact that supersymmetric theories often exhibit flat directions. At the renormalizable level, the MSSM possesses many flat directions. A simple example is

$$H_u = \begin{pmatrix} 0 \\ v \end{pmatrix} \quad L_1 = \begin{pmatrix} v \\ 0 \end{pmatrix}. \quad (19.98)$$

This direction is characterized by a modulus which carries lepton number. Written in a gauge-invariant fashion, $\Phi = H_u L$. As we have seen, producing a lepton number is for all intents and purposes like producing a baryon number. Non-renormalizable, higher-dimension terms, with more fields, can lift the flat direction. For example, the quartic term in the superpotential:

$$\mathcal{L}_4 = \frac{1}{M} (H_u L)^2 \quad (19.99)$$

respects all of the gauge symmetries and is invariant under $R$-parity. It gives rise to a potential

$$V_{\text{lift}} = \frac{|v|^6}{M^2}. \quad (19.100)$$

There are many more flat directions, and many of these do carry baryon or lepton number. A flat direction with both baryon and lepton number excited is the following:

First generation: $Q^1_1 = b$, $\bar{u}_2 = a$, $L_2 = b \quad (19.101)$

Second: $\bar{d}_1 = \sqrt{|b|^2 + |a|^2} \quad (19.102)$

Third: $\bar{d}_3 = a. \quad (19.103)$

(On $Q$, the upper index is a color index, the lower index an $SU(2)$ index, and we have suppressed the generation indices.)

Higher-dimension operators again can lift this flat direction. In this case the leading term is:

$$\mathcal{L}_7 = \frac{1}{M^5} [Q^1 L^2][\bar{u}^1 \bar{d}^2 \bar{d}^3]. \quad (19.104)$$

Here the superscripts denote flavor. We have suppressed color and $SU(2)$ indices, but the braces indicate sets of fields which are contracted in $SU(3)$ and $SU(2)$ invariant ways. In addition to being completely gauge-invariant, this operator is invariant under ordinary $R$-parity. (There are lower-dimension operators, including operators of dimension 4, which violate $R$-parity.) It gives rise to a term in the
potential:

\[ V_{\text{lift}} = \frac{\Phi^{10}}{M^6}. \]  \hspace{1cm} (19.105)

Here \( \Phi \) refers in a generic way to the fields whose vevs parameterize the flat directions \((a,b)\).

### 19.7 Supersymmetry breaking in the early universe

We have indicated that higher-dimension, supersymmetric operators give rise to potentials in the flat directions. To fully understand the behavior of the fields in the early universe, we need to consider supersymmetry breaking, which gives rise to additional potential terms.

In the early universe, we expect supersymmetry is much more badly broken than it is in the present era. For example, during inflation, the non-zero energy density (cosmological constant) breaks supersymmetry. Suppose that \( I \) is the inflaton field, and that the inflaton potential arises because of a non-zero value of the auxiliary field for \( I, F_I = \partial W / \partial I \). So, during inflation, supersymmetry is broken by a large amount. Not surprisingly, as a result, there can be an appreciable supersymmetry-breaking potential for \( \Phi \). These contributions to the potential have the form:

\[ V_H = H^2 \Phi^2 f\left(\frac{\Phi^2}{M_P^2}\right). \]  \hspace{1cm} (19.106)

It is perfectly possible for the second derivative of the potential near the origin to be negative. In this case, writing our higher-dimension term as:

\[ W_n = \frac{1}{M^n} \Phi^{n+3}. \]  \hspace{1cm} (19.107)

the potential takes the form

\[ V = -H^2|\Phi|^2 + \frac{1}{M^{2n}}|\Phi|^{2n+4}. \]  \hspace{1cm} (19.108)

The minimum of the potential then lies at:

\[ \Phi_0 \approx M \left(\frac{H}{M}\right)^{\frac{1}{n+1}}. \]  \hspace{1cm} (19.109)

More generally, one can see that the higher the dimension of the operator that raises the flat direction, the larger the starting value of the field – and the larger the ultimate value of the baryon number. Typically, there is plenty of time for the field to find its minimum during inflation. After inflation, \( H \) decreases, and the field \( \Phi \) evolves adiabatically, oscillating slowly about the local minimum for some time.
Our examples illustrate that in models with $R$-parity, the value of $n$, and hence the size of the initial field, can vary appreciably. Which flat direction is most important depends on the form of the mass matrix (i.e. on which directions the curvature of the potential is negative). With further symmetries, it is possible that $n$ is larger, and even that all operators which might lift the flat direction are forbidden. For the rest of this section we will continue to assume that the flat directions are lifted by terms in the superpotential. If they are not, the required analysis is different, since the lifting of the flat direction is entirely associated with supersymmetry breaking.

### 19.7.1 Appearance of the baryon number

The term in the potential, $|\partial W/\partial \Phi|^2$, does not break either baryon number or CP. In most models, it turns out that the leading sources of $B$ and CP violation come from supersymmetry-breaking terms associated with $F_I$. These have the form

$$am_{3/2}W + bHW.$$  \hspace{1cm} (19.110)

Here $a$ and $b$ are complex, dimensionless constants. The relative phase in these two terms, $\delta$, violates CP. This is crucial; if the two terms carry the same phase, then the phase can be eliminated by a field redefinition, and we have to look elsewhere for possible CP-violating effects. Examining Eqs. (19.99) and (19.104), one sees that the term proportional to $W$ violates $B$ and/or $L$. In following the evolution of the field $\Phi$, the important era occurs when $H \approx m_{3/2}$. At this point, the phase misalignment of the two terms, along with the $B$-violating coupling, leads to the appearance of a baryon number. From the equations of motion, the equation for the time rate of change of the baryon number is

$$\frac{dn_B}{dt} = \sin(\delta)\frac{m_{3/2}}{M^n} \Phi_{n+3}^n.$$  \hspace{1cm} (19.111)

Assuming that the relevant time is $H^{-1}$, one is led to the estimate (supported by numerical studies)

$$n_B = \frac{1}{M^n} \sin(\delta) \Phi_{n+3}^n.$$  \hspace{1cm} (19.112)

Here, $\Phi_0$ is determined by $H \approx m_{3/2}$, i.e. $\Phi_{0+2}^{2n} = m_{3/2}^2 M^{2n}$.

### 19.8 The fate of the condensate

Of course, we don’t live in a universe dominated by a coherent scalar field. In this section, we consider the fate of a homogeneous condensate, ignoring possible
inhomogeneities. The following section will deal with inhomogeneities, and the interesting array of phenomena to which they might give rise.

We will adopt the following model for inflation. The features of this picture are true of many models of inflation, but by no means all. We will suppose that the energy scale of inflation is \( E \approx 10^{15} \text{ GeV} \). We assume that inflation is due to a field, the inflaton \( I \). The amplitude of the inflaton, just after inflation, we will take to be of order \( M \approx 10^{18} \text{ GeV} \) (the usual reduced Planck mass). Correspondingly, we will take the mass of the inflaton to be \( m_I = 10^{12} \text{ GeV} \) (so that \( m_I^2 M_p^2 \approx E^4 \)). Correspondingly, the Hubble constant during inflation is of order \( H_I \approx E^2 / M_p \approx 10^{12} \text{ GeV} \).

After inflation ends, the inflaton oscillates about the minimum of its potential, much like the field \( \phi_1 \), until it decays. We will suppose that the inflaton couples to ordinary particles with a rate suppressed by a single power of the Planck mass. Dimensional analysis then gives for the rough value of the inflaton lifetime:

\[
\Gamma_I = \frac{m_I^3}{M^2} \sim 1 \text{ GeV}.
\] (19.113)

The reheating temperature can then be obtained by equating the energy density at time \( H \approx \Gamma (\rho = 3 H^2 M^2) \) to the energy density of the final plasma:

\[
T_R = T(t = \Gamma_I^{-1}) \sim (\Gamma_I M_p)^{1/2} \sim 10^9 \text{ GeV}.
\] (19.114)

The decay of the inflaton is actually not sudden, but leads to a gradual reheating of the universe, as described, for example, in the book by Kolb and Turner (1990). As a function of time \( (H) \):

\[
T \approx (T_R^2 H(t) M_p)^{1/4}.
\] (19.115)

As for the field \( \Phi \), our basic assumption is that during inflation, it obtains a large value, in accord with Eq. (19.109). When inflation ends, the inflaton, by assumption, still dominates the energy density for a time, oscillating about its minimum; the universe is matter dominated during this period. The field \( \Phi \) now oscillates about a time-dependent minimum, given by Eq. (19.109). The minimum decreases in value with time, dropping to zero when \( H \sim m_3^2 / 2 \). During this evolution, a baryon number develops classically. This number is frozen once \( H \sim m_3^2 / 2 \).

Eventually the condensate will decay, through a variety of processes. As we have stressed, the condensate can be thought of as a coherent state of \( \Phi \) particles. These particles – linear combinations of the squark and slepton fields – are unstable and will decay. However, for \( H \leq m_3^2 / 2 \), the lifetimes of these particles are much longer than in the absence of the condensate. The reason is that the fields to which \( \Phi \) couples have mass of order \( \Phi \), and \( \Phi \) is large. In most cases, the most important
19.8 The fate of the condensate

The fate of the condensate is what we might call evaporation: particles in the ambient thermal bath can scatter off of the particles in the condensate, leaving final states with only ordinary particles.

We can make a crude estimate for the reaction rate as follows. Because the particles which couple directly to $\Phi$ are heavy, interactions of $\Phi$ with light particles must involve loops. So we include a loop factor in the amplitude, of order $\alpha^2$, the weak coupling squared. Because of the large masses, the amplitude is suppressed by $\Phi$. Squaring, and multiplying by the thermal density of scattered particles, gives:

$$\Gamma_p \sim \alpha^2 \frac{1}{\Phi^2} \left( T_R^2 H M \right)^{3/4}.$$  \hspace{1cm} (19.116)

The condensate will evaporate when this quantity is of order $H$. Since we know the time dependence of $\Phi$, this allows us to solve for this time. One finds that equality occurs, in the case $n = 1$, for $H_I \sim 10^2 - 10^3$ GeV. For $n > 1$, it occurs significantly later (for $n < 4$, it occurs before the decay of the inflaton; for $n \geq 4$, a slightly different analysis is required than that which follows). In other words, for the case $n = 1$, the condensate evaporates shortly after the baryon number is created, but for larger $n$, it evaporates significantly later.

The expansion of the universe is unaffected by the condensate as long as the energy density in the condensate, $\rho_\Phi \sim m_\Phi^2 \Phi^2$, is much smaller than that of the inflaton, $\rho_I \sim H^2 M^2$. Assuming that $m_\Phi \sim m_{3/2} \sim 0.1-1$ TeV, a typical supersymmetry breaking scale, one can estimate the ratio of the two densities at the time when $H \sim m_{3/2}$ as

$$\frac{\rho_\Phi}{\rho_I} \sim \left( \frac{m_{3/2}}{M_p} \right)^{2/(n+1)}.$$  \hspace{1cm} (19.117)

We are now in a position to calculate the baryon to photon ratio in this model. Given our estimate of the inflaton lifetime, the coherent motion of the inflaton still dominates the energy density when the condensate evaporates. The baryon number is just the $\Phi$ density just before evaporation divided by the $\Phi$ mass (assumed of order $m_{3/2}$), while the inflaton number is $\rho_I/M_I$. So the baryon to inflaton ratio follows from Eq. (19.117). With the assumption that the inflaton energy density is converted to radiation at the reheating temperature, $T_R$, we obtain:

$$\frac{n_B}{n_\gamma} \sim \frac{n_B}{(\rho_I/T_R)} \sim \frac{n_B}{n_\Phi n_\Phi} \frac{T_R \rho_\Phi}{T_R} \sim 10^{-10} \left( \frac{T_R}{10^9 \text{ GeV}} \right) \left( \frac{M_p}{m_{3/2}} \right)^{\frac{3}{(n+1)} \frac{3}{(n+1)}}.$$  \hspace{1cm} (19.118)

Clearly the precise result depends on factors beyond those indicated here explicitly, such as the precise mass of the $\Phi$ particle(s). But as a rough estimate, it is rather robust. For $n = 1$, it is in precisely the right range to explain the observed baryon
asymmetry. For larger \( n \), it can be significantly larger. In light of our discussion of late decays of moduli this is potentially quite interesting. These decays produce a huge amount of entropy, typically increasing the entropy by a factor of \( 10^7 \) or so. The baryon density is diluted by a corresponding factor. But we see that coherent production can readily yield baryon to photon densities, prior to moduli decay, of the needed size.

There are many other issues which can be studied, both in leptogenesis and in Affleck–Dine baryogenesis, but it appears that both types of process might well account for the observed baryon asymmetry. The discovery (or not) of low-energy supersymmetry, and further studies of neutrino masses, might make one or the other picture more persuasive. Both pose challenges, as they involve couplings which we are not likely to measure directly.

19.9 Dark energy

It has long been recognized that any cosmological constant in nature is far smaller than scales of particle physics. Before the discovery of the dark energy, many physicists conjectured that for some reason of principle, this energy is zero. However, it is now clear that the energy is non-zero, and in fact that this dark energy is the largest component of the energy density of the universe. Present data is compatible with the idea that this energy density represents a cosmological constant \((w = -1)\), but other suggestions, typically involving time-varying scalar fields, have been offered.

Apart from its smallness, another puzzle surrounding the cosmological constant is simply one of coincidence: why is the dark energy density today comparable to the dark matter density? Weinberg has argued that it couldn’t be much different than this in a universe containing stars and galaxies, provided all of the other laws of nature are as we observe. The basic point is that if the dark energy were, say, \( 10^3 \) times more dense than we observe, it would have come to dominate the energy density when the universe was much younger than it is today – prior to the formation of galaxies and stars. The rapid acceleration after that time would have prevented the formation of structure. More refined versions of the argument give estimates for the dark energy within a factor of ten of the measured value.

Weinberg speculated that perhaps the universe is much larger than we see (our current horizon). In other regions, it has different values of the cosmological constant. Only in those regions where \( \Lambda \) is very small would stars – and hence observers – form. Weinberg called this possible explanation (actually prediction) of \( \Lambda \) the weak anthropic argument. We will return to this question in our studies of string theory, where we will see that such a landscape of ground states may exist.
Suggested reading

Seminal papers on inflation include that of Guth (1981), which proposed a version of inflation now often referred to as “old inflation,” and those of Linde (1982) and Albrecht and Steinhardt (1982), which contain the germ of the slow roll inflation idea stressed in this work. The ideas of hybrid inflation were developed by Linde (1994); those specifically discussed here were introduced by Randall et al. (1996) and Berkooz et al. (2004). There are a number of good texts on inflation and related issues, some of which we have mentioned in the previous chapter. These include those of Dodelson (2004), Kolb and Turner (1990), and Linde (1990). Dodelson provides a particularly up to date discussion of dark matter, including more detailed calculations than those presented here, and dark energy, including surveys of observational results. For a review of axions and their cosmology and astrophysics, see Turner (1990). For more recent papers which raise questions about the cosmological axion limits, see, for example, Banks et al. (2003). The cosmological moduli problem, and possible solutions, were first discussed by Banks et al. (1994) and de Carlos et al. (1993). A general review of electroweak baryogenesis, including detailed discussions of phenomena at the bubble walls, appears in Cohen et al. (1993). A discussion of electroweak baryogenesis within the MSSM appears in Carena et al. (2003). A detailed review of baryogenesis appears in Buchmuller et al. (2005), while Enqvist and Mazumdar (2003) focuses on Affleck–Dine baryogenesis. A more comprehensive review of baryogenesis mechanisms appears in Dine and Kusenko (2003). Aspects of the cosmological constant, and especially Weinberg’s anthropic prediction of $\Lambda$, are explained clearly in Weinberg (1989), with more recent additions in Vilenkin (1995) and Weinberg (2000).

Exercises

1. Verify the slow roll conditions, Eqs. (19.12) and (19.13). Determine the number of $e$-foldings and the size of $\delta \rho / \rho$ as a function of $N$.

2. Work through the limits on the axion in more detail. Try to analyze the behavior of the axion energy in the high-temperature regime.

3. Construct a discrete $R$-symmetry which guarantees that the $H_U L$ flat direction is exactly flat. Assuming that the universe reheats to 100 MeV when a modulus decays, estimate the final baryon number of the universe in this case.

4. Suppose that the characteristic scale of supersymmetry breaking is much higher than 1 TeV, say $10^9$ GeV. Discuss baryogenesis by coherent scalar fields in such a situation.
Part 3

String theory
String theory was stumbled on, more or less, by accident. In the late 1960s, string theories were first proposed as theories of the strong interactions. But, it was quickly realized that, while hadronic physics has a number of string-like features, string theories were not suitable for a detailed description. In their simplest form, string theories had massless spin-two particles and more than four dimensions of space-time, hardly features of the strong interactions. But a small group of theorists appreciated that the presence of a spin-two particle implied that these theories were generally covariant and explored them through the 1970s and early 1980s as possible theories of quantum gravity. Like field theories, the number of possible string theories seemed to be infinite, while, unlike field theories, there was reason to believe that these theories did not suffer from ultraviolet divergences. In the 1980s, however, studies of anomalies in higher dimensions suggested that all string theories with chiral fermions and gauge interactions suffered from quantum anomalies. But in 1984, it was shown that anomalies cancel for two choices of gauge group. It was quickly recognized that the non-anomalous string theories do come close to unifying gravity and the Standard Model of particle physics. Many questions remained. Beginning in 1995, great progress was made in understanding the deeper structure of these theories. All of the known string theories were understood to be different limits of some larger structure. As string theories still provide the only framework in which one can do systematic computations of quantum gravity effects, many workers use the term “string theory” to refer to some underlying structure which unifies quantum mechanics, gravity and gauge interactions.

String theory has provided us with many insights into what a fundamental theory of gravity and gauge interactions might look like, but there is still much we do not understand. We can’t begin a course by enunciating some great principle and seeing what follows. We might, for example, have imagined that the underlying theory would be a string field theory, whose basic objects would be objects which would create and annihilate strings. Some set of organizing principles would
determine the action for this system, and the rest would be a problem of working out the consequences. But there are good reasons to believe that string theory is not like this. Instead, we can at best provide a collection of facts, organized according to the teacher/author/professor’s view of the subject at any given moment. As a result, it is perhaps useful first to give at least some historical perspective as to how these facts were accumulated, if only to show that there are, as of yet, no canonical texts or sacred principles in the subject. In the next section, we review a bit of the remarkable history of string theory. In the following section, we will attempt to survey what is known as of this writing: the various string theories, with their spectra and interactions, and the connections between them.

20.1 The peculiar history of string theory

For electrodynamics, the passage from classical to quantum mechanics is reasonably straightforward. But general relativity and quantum mechanics seem fundamentally incompatible. Viewed as a quantum field theory, Einstein’s theory of general relativity is a non-renormalizable theory; its coupling constant (in four dimensions) has dimensions of inverse mass-squared. As a result, quantum corrections are very divergent. From the point of view developed in Part 1, these divergences should be thought of as cut off at some scale associated with new physics; general relativity is an incomplete theory. Hawking has discussed another sense in which gravity and quantum mechanics seem to clash. Hawking’s paradox appears to be associated with phenomena at arbitrarily large distances – in particular, with the event horizons of large black holes. Because black holes emit a thermal spectrum of radiation, it seems possible for a pure state – a large black hole – to evolve into a mixed state. These puzzles suggest that reconciling quantum mechanics and gravity will require a radical rethinking of our understanding of very short-distance physics.

Apart from its potential to reconcile quantum mechanics and general relativity, there is another reason that string theory has attracted so much attention: it is finite, free of the ultraviolet divergences that plague ordinary quantum field theories. In the previous chapters of this book, we have adopted the point of view that our theories of nature should be viewed as effective theories. It is not clear that they can be complete in any sense. One might wonder whether some sort of structure exists where the process stops; where some finite, fundamental theory accounts for the features of our present, more tentative constructions. Many physicists have speculated through the years that these two questions are related; that an understanding of quantum general relativity would provide a fundamental length scale. The finiteness of string theory suggests it might play this role.
String theory was discovered, by accident, in the 1960s, as physicists tried to understand certain regularities of the hadronic $S$-matrix. In particular, hadronic scattering amplitudes exhibited a feature then referred to as “duality.” Scattering amplitudes with two incoming and two outgoing particles (so-called $2 \rightarrow 2$ processes) could be described equally well by an exchange of mesons in the $s$ channel or in the $t$ channel (but not both simultaneously). This is not a property, at least perturbatively, of conventional quantum field theories. Veneziano succeeded in writing an expression for an $S$-matrix with just the required properties. Veneziano’s result was extended in a variety of ways and it was soon recognized (by Nambu, Susskind and others) that this model was equivalent to a theory of strings.

One could well imagine coming to string theory by a different route. Quantum field theory describes point particles. Apart from properties like mass and charge, no additional features (size, shape) are assigned to the basic entities. One could well imagine that this is naive, but in describing nature, quantum field theory is extraordinarily successful. In fact, there is no evidence for any size of the electron or the quarks down to distances of order $10^{-17}$ cm (energy scales of order several TeV). Still, it is natural to try to go beyond the idea of particles as points. The simplest possibility is to consider entities with a one-dimensional extent, strings. In the next chapters, we will discuss the features of theories of string. Here we just note that a straightforward analysis yields some remarkable results. A relativistic quantum string theory is necessarily:

1. a theory of general relativity;
2. a theory with gauge interactions;
3. finite: string world sheets are smooth. Strings do not interact at space-time points. As a result, in perturbation theory, one does not have the usual ultraviolet divergences of quantum theories of relativistic particles.

These features are not postulated; they are inevitable. Other, seemingly less desirable, features also emerge: the space-time dimension has to be 26 or 10. Many string theories also contain tachyons in their spectrum, whose interpretation is not immediately clear.

As theories of hadronic physics, string theories had only limited success. Their spectra and $S$-matrices did share some features in common with those of the real strong interactions. But as a result of the features described above – massless particles and unphysical space-time dimensions as well as the presence of tachyons in many cases – strings were quickly eclipsed by QCD as a theory of the strong interactions.

Despite these setbacks, string theory remained an intriguing topic. String theories were recognized to have short distance behavior much different – and better – than that of quantum field theories. There was reason to think that such theories were free
of ultraviolet divergences altogether. Scherk and Schwarz, and also Yoneya, made the bold proposal that string theories might well be sensible theories of quantum gravity. At the time, any concrete realization of this suggestion seemed to face enormous hurdles. The first string theories contained bosons only. But string theories with fermions were soon studied, and were discovered to have another remarkable, and until then totally unfamiliar, property: supersymmetry. We have already learned a great deal about supersymmetry, but at this early stage, its possible role in nature was completely unclear. In their early formulations, string theories only made sense in special – and at first sight uninteresting – space-time dimensions. But it had been conjectured since the work of Kaluza and Klein that higher-dimensional space-times might be “compactified,” leaving theories which appear four-dimensional, and Scherk and Schwarz hypothesized that this might be the case for string theories. Over a decade, Green and Schwarz studied the supersymmetric string theories further, developing a set of calculational tools in which supersymmetry was manifest, and which were suitable for tree-level and one-loop computations. Witten and Alvarez-Gaume, however, pointed out that higher-dimensional theories in general suffer from anomalies, which render them inconsistent. They argued that almost all of the then-known chiral string theories suffered from just such anomalies. It appeared that the string program was doomed; only two known string theories, theories without gauge interactions, seemed to make sense. Green and Schwarz, however, persisted. By a direct string computation, they discovered that, while it was true that almost all would-be string theories with gauge symmetries are inconsistent, there was one exception among the then-known theories, with a gauge group $O(32)$. They reviewed the standard anomaly analysis and realized why $O(32)$ is special; this work raised the possibility that there might be one more consistent string theory, based on the gauge group $E_8 \times E_8$. The corresponding string theory, as well as another with gauge group $O(32)$ (known as the heterotic string theories), was promptly constructed.

This work stimulated widespread interest in string theory as a unified theory of all interactions, for now these theories appeared to be not only finite theories of gravity, but also nearly unique. Compactification of the heterotic string on six-dimensional manifolds known as Calabi–Yau spaces were quickly shown to lead to theories which at low energies closely resemble the Standard Model, with similar gauge groups, particle content, and other features such as repetitive generations, low-energy supersymmetry and dynamical supersymmetry breaking. The various string theories have since been shown to be part of a larger theory, suggesting that one is studying some unique structure which describes quantum gravity. Some of the basic questions about quantum gravity theories, such as Hawking’s puzzle, have been, at least partially, resolved.
Many questions remain, however. There is still no detailed understanding of how string theory can make contact with experiment. There are a number of reasons for this. String theory, as we will see, is a theory with no dimensionless parameters. This is a promising beginning for a possible unified theory. But it is not clear how a small expansion parameter can actually emerge, allowing systematic computation. String theory provides no simple resolution of the cosmological constant puzzle. Finally, while there are solutions which resemble nature, there are vastly more which don’t. A principle, or dynamics, which might explain the selection of one vacuum or another, has not emerged.

Yet string theory is the only model we have for a quantum theory of gravity. More than that, it is the only model we have for a finite theory, which could be viewed as some sort of ultimate theory. At the same time, string theory addresses almost all of the deficiencies we have seen in the Standard Model, and has the potential to encompass all of the solutions we have proposed. The following are some examples.

1. The theory unifies gravity and gauge interactions in a consistent, quantum mechanical framework.
2. The theory is completely finite. It has no free parameters. The constants of nature must be determined by the dynamics, or other features internal to the theory.
3. The theory possesses solutions in which space-time is four-dimensional, with gauge groups close to the Standard Model and repetitive generations. It is in principle possible to compute the parameters of the Standard Model.
4. Many of the solutions exhibit low-energy supersymmetry, of the sort we have considered in the first part of this book.
5. Other solutions exhibit large dimensions, technicolor-like structures, and the like.
6. The theory does not have continuous global symmetries, but often possesses discrete symmetries, of the sorts we have considered.

While these are certainly encouraging signs, as we will learn in the third part of this book, we are a long way from a detailed understanding of how string theory might describe nature. We will see that there are fundamental obstacles to such an understanding. At the same time, we will see that string theory provides a useful framework in which to assess proposals for beyond the Standard Model physics.

The third part of this book is intended to provide the reader with an overview of superstring theory, with a view to connecting string theory with nature. In the next chapter, we will study the bosonic string. We will understand how to find the spectra of string theories. We will also understand string interactions. The reason that string theories are so constrained is that strings can only interact in a limited set of ways, essentially by splitting and joining. We will explain how to translate this into concrete computations of scattering amplitudes.
In subsequent chapters, we will turn to the superstring theories, obtaining their spectra and understanding their interactions. We will then turn to compactification of string theories, focussing mainly on compactifications to four dimensions. We first consider toroidal compactifications of strings, whose features can be worked out quite explicitly. We also discuss orbifolds, simple string models which can exhibit varying amounts of supersymmetry. Then we devote a great deal of attention to compactifications on Calabi–Yau spaces. These are smooth spaces; superstring theories compactified on these spaces exhibit varying amounts of supersymmetry. Many look quite close to the real world.

Finally, we will turn to the question of developing a realistic string phenomenology. Having seen the many intriguing features of string models, we will point out some of the challenges. These are as follows.

1. The proliferation of classes of string vacua.
2. Within different classes, the existence of moduli.
3. Mechanisms which generate potentials for moduli are known, but in regimes where calculations can be performed systematically, tend not to produce stable minima. The question of supersymmetry breaking is closely related to the question of stabilizing moduli.
4. There are detailed issues, such as proton decay, features of quark and lepton masses, and many others.

We will touch on some proposed solutions to these puzzles. Much string model building simply posits that moduli have been fixed in some way, and a vacuum with desirable properties is somehow selected by some (unknown) overarching principle. This is often backed up by calculations, which, while not systematic, are at least suggestive that moduli are stabilized. An alternative viewpoint is provided by the “landscape.” Here, one starts with the observation that introducing fluxes for various tensor fields can potentially stabilize moduli. The possible choices of flux vastly increase the possible array of (metastable) string ground states. If one simply accepts that there is such a landscape of states, and that the universe samples many of these states in some way, then one is led to think about distributions of parameters of low-energy physics, not merely the coupling constants, but the gauge groups, particle content, scale of supersymmetry breaking, and value of the cosmological constant. For better or worse, this is in some sense the ultimate realization of the notions of naturalness which so concerned us in Part 1. The question is why we are the likely outcome of a distribution of this sort. We will leave it for the readers – and for experiment – to sort out which, if any, of these viewpoints may be correct.

This is not a string theory textbook. The reader will not emerge from these few chapters with the level of technical proficiency in weakly coupled strings provided by Polchinski’s text, or with the expertise in Calabi–Yau spaces provided by the
book of Green, Schwarz and Witten (1987). In order to quickly obtain the spectra of various string theories, the following chapters heavily emphasize light cone techniques. While some aspects of the covariant treatment are developed in order to explain the rules for computing the $S$-matrix, many important topics, especially the Polyakov path integral approach and BRST quantization, are given only cursory treatment. Similarly, the introduction to $D$-brane physics provides some basic tools, but does not touch on much of the well-developed machinery of the subject. The reader who wishes a more thorough grounding in the physics of $D$-branes will want to consult the texts of Polchinski (1998) and of Johnson (2003).

**Suggested reading**

The introduction of the book by Green *et al.* (1987) provides a particularly good overview of the history of string theory, and some of its basic structure. The introductory chapter of Polchinski’s text (1998) provides a good introduction to more recent developments, and a perspective on why strings might be important in the description of nature.
Consider a particle moving through space. As it moves, it sweeps out a path called a world line. The action of the particle is just the integral of the invariant length element along the path, up to a constant.

Suppose we want to describe the motion of a string. A string, as it moves, sweeps out a two-dimensional surface in space-time called a world sheet. We can parameterize the path in terms of two coordinates, one time-like and one space-like, denoted \( \sigma \) and \( \tau \), or \( \sigma_0 \) and \( \sigma_1 \). The action should not depend on the coordinates we use to parameterize the surface. Polyakov stressed that this can be achieved by using the formalism of general relativity. Introduce a two-dimensional metric, \( \gamma_{\alpha \beta} \).

Then an invariant action is:

\[
S = \frac{T}{2} \int d^2 \sigma \sqrt{-\gamma} \gamma^{\alpha \beta} \partial_\alpha X^\mu \partial_\beta X^\nu \eta_{\mu \nu}.
\]

(21.1)

Here our conventions are such that for a flat space,

\[
\gamma = \eta = \begin{pmatrix} -1 & 0 \\ 0 & 1 \end{pmatrix}
\]

(21.2)

(similarly, our \( D \)-dimensional space-time metric is \( ds^2 = -dt^2 + d\mathbf{x}^2 \)).

This action has a large symmetry group. There are, first, general coordinate transformations of the two-dimensional surface. For a simple topology (plane or sphere), these permit us to bring the metric to the form:

\[
\gamma = e^\phi \eta.
\]

(21.3)

In this gauge (the conformal gauge) the action is independent of \( \phi \):

\[
S = \frac{-T}{2} \int d^2 \sigma \eta^{\alpha \beta} \partial_\alpha X^\mu \partial_\beta X^\nu \eta_{\mu \nu}.
\]

(21.4)

It is possible to fix this symmetry further. To motivate this gauge choice, we consider an analogous problem in field theory. In a gauge theory like \( QED \), we can
21 The bosonic string

fix a covariant gauge, $\partial \cdot A = 0$. This gauge fixing, while manifestly Lorentz invariant, is not manifestly unitary. We might try to quantize covariantly by introducing creation and annihilation operators, $a^\mu$. These would obey:

$$[a^\mu, a^{\dagger \nu}] = g^{\mu\nu}$$

so that some states seem to have negative norm. If one proceeds in this way, it is necessary to prove that states with negative (or vanishing) norm can’t be produced in scattering amplitudes.

One way to deal with this is to choose a non-covariant gauge. Coulomb gauge is a familiar example, but a particularly useful description of gauge theories is obtained by choosing the “light cone gauge.” First, define light cone coordinates:

$$x^\pm = \frac{1}{\sqrt{2}}(x^0 \pm x^{D-1}).$$

The remaining, transverse coordinates, we will simply denote as $\vec{X}$. Correspondingly, one defines the light cone momenta:

$$p^\pm = \frac{1}{\sqrt{2}}(p^0 \pm p^{D-1}), \quad \vec{p}.$$  (21.7)

Note that

$$A \cdot B = -(A^+ B^- + A^- B^+) + \vec{A} \cdot \vec{B}.$$  (21.8)

Now we will think of $x^+$ as our time variable. The “Hamiltonian” generates translations in $x^+$; it is in fact $p^-$. Note that for a particle:

$$p^2 = -2p^+ p^- + \vec{p}^2.$$  (21.9)

The Hamiltonian is:

$$H = \frac{1}{p^+} p.$$  (21.10)

Having made this choice of variables, one can then make the gauge choice $A^+ = 0$. In the Lagrangian, there are no terms involving $\partial_+ A^-$, so $A^-$ is not a dynamical field; only the $D - 2$ $A^i$s are dynamical. So we have the correct number of physical degrees of freedom. One simply solves for $A^-$ by its equations of motion. In the early days of QCD, this description proved very useful in understanding very-high-energy scattering. In practice, similar algebraic gauges are still very useful.

Light cone coordinates, more generally, are very helpful for identifying physical degrees of freedom. Consider the problem of counting the degrees of freedom associated with some tensor field, $A^{\mu\nu\rho}$. For a massive field, one counts by going to the rest frame, and restricting the indices $\mu, \nu, \rho$ to be $D - 1$ dimensional. For a massless field, the relevant group is the “little group” of the Lorentz group, $SO(D - 2)$. Correspondingly, one restricts the indices to be $D - 2$ dimensional. So, for example,
for a massless vector, there are $D - 2$ degrees of freedom. For a symmetric, traceless
tensor (the graviton), there are $[(D - 2)(D - 1)/2] - 1$. Light cone coordinates,
and light cone gauge, provide an immediate realization of this counting.

For many questions in quantum field theory, covariant methods are much more
powerful than the light cone. Quantum field theorists are familiar with techniques
for coping with covariant gauges. These involve introduction of additional fictitious
degrees of freedom (Faddeev–Popov ghosts). It is probably fair to say that most do
not know much about gauges like the light cone gauge (there is almost no treatment
of these topics in standard texts). But we will see in string theory that the light cone
gauge is quite useful in isolating the physical degrees of freedom of strings. It lacks
some of the elegance of covariant treatments, but it avoids the need to introduce an
intricate ghost structure, and, as in field theory, the physical degrees of freedom are
manifest. The differences between the covariant and light cone treatments, as we
will see, are most dramatic when we consider supersymmetric strings. In the light
cone approach of Green and Schwarz, space-time supersymmetry is manifest. In
the covariant approach, it is not at all apparent. On the other hand, for the discussion
of interactions, the light cone treatment tends to be rather awkward. In this chapter,
we will first introduce the light cone gauge, and then go on to discuss aspects of
the covariant formulation. The suggested readings will satiate the reader interested
in more details of the covariant treatment.

21.1 The light cone gauge in string theory

21.1.1 Open strings

In the conformal gauge, we can use our coordinate freedom to choose $X^+ = \tau$. We
also can choose the coordinates such that the momentum density, $P^+$, is constant
on the string. In this gauge, in $D$ dimensions, the independent degrees of freedom
of a single string are the coordinates, $X^I(\sigma, \tau)$, $I = 1, \ldots, D - 2$. They are each
described by the Lagrangian of a free two-dimensional field:

$$S = \frac{T}{2} \int d^2\sigma (\partial_\tau X^I)^2 - (\partial_\sigma X^I)^2). \quad (21.11)$$

It is customary to define another quantity, $\alpha'$ (the “Regge slope”), with dimensions
of length-squared:

$$\alpha' = \frac{1}{2\pi T}. \quad (21.12)$$

We will generally take a step further and use units with $\alpha' = 1/2$. In this case, the
action is:

$$S = \frac{-1}{2\pi} \int d^2\sigma (\partial_\tau X^I)^2 - (\partial_\sigma X^I)^2). \quad (21.13)$$
The reader should be alerted that there is another common choice of units: $\alpha' = 2$, and we will encounter this later. In this case, the action has a $1/8\pi$ out front.

In order to write equations of motion, we need to specify boundary conditions in $\sigma$. Consider, first, open strings, i.e. strings with two free ends. We want to choose boundary conditions so that when we vary the action we can ignore surface terms. There are two possible choices.

1. Neumann boundary conditions,

\[ \partial_\sigma X^I(\tau, 0) = \partial_\sigma X^I(\tau, \pi) = 0. \] (21.14)

2. Dirichlet boundary conditions:

\[ X^I(\tau, 0) = X^I(\tau, \pi) = \text{constant}. \] (21.15)

It is tempting to discard the second possibility, as it appears to violate translation invariance. For now, we consider only Neumann boundary conditions, but we will return later to Dirichlet.

We want to write a Fourier expansion for the $X^I$s. The normalization of the coefficients is conventionally taken to be somewhat different than that of relativistic quantum field theories:

\[ X^I = x^I + p^I/\tau + i \sum_{n \neq 0} \frac{1}{n} \alpha^I_n e^{-in\tau} \cos(n\sigma). \] (21.16)

The $\alpha^\mu_n$s are, up to constants, ordinary creation and annihilation operators:

\[ \alpha^I_n = \sqrt{n}a_n \quad \alpha^I_{-n} = \sqrt{n}a^\dagger_n. \] (21.17)

Because we are working at finite volume (in the two-dimensional sense) there are normalizable zero modes, the $x^I$s and $p^I$s. They correspond to the coordinate and momentum of the center of mass of the string. From our experience in field theory, we know how to quantize this system. We impose the commutation relations:

\[ [\partial_\tau X^I(\sigma, \tau), X^J(\sigma', \tau)] = \frac{-i}{\pi} \delta^{IJ}(\sigma - \sigma'). \] (21.18)

This is satisfied by:

\[ [x^I, p^J] = i\delta^{IJ} \quad [\alpha^I_n, \alpha^J_{n'}] = n\delta_{n+n',0}\delta^{IJ}. \] (21.19)

The states of this theory can be labeled by their transverse momenta, $\vec{p}$, and by integers corresponding to the occupation numbers of the infinite set of oscillator modes. It is helpful to keep in mind that this is just the quantization of a set of free, two-dimensional fields in a finite volume.
21.1 The light cone gauge in string theory

We can write a Hamiltonian for this system. Normal ordering:

\[ H = \vec{p}^2 + N + a \]  

(21.20)

where

\[ N = \sum_{n=1}^{\infty} \alpha_n^l \alpha_n^l, \]  

(21.21)

and \( a \) is a normal ordering constant. States can be labelled by the occupation numbers for each mode, \( N_n \), and the momentum, \( p^l \),

\[ |p^l, \{N_n\}\rangle \]  

(21.22)

The light cone Hamiltonian, \( H \), generates translations in \( \tau \). It is convenient to refine the gauge choice:

\[ X^+ = p^+ \tau. \]

Since \( p^- \) is conjugate to the light cone time, \( x^+ \),

\[ p^- = H/p^+, \]  

(21.23)

or

\[ p^+ p^- = \vec{p}^2 + N + a, \quad M^2 = N + a. \]  

(21.24)

So the quantum string describes a tower of states, of arbitrarily large mass. The constant \( a \) is not arbitrary. We will see shortly that

\[ a = -1. \]  

(21.25)

This means that the lowest state is a tachyon. We can label this state simply

\[ |T(\vec{p})\rangle = |\vec{p}, \{0\}\rangle \equiv |\vec{p}\rangle. \]  

(21.26)

The state carries transverse momentum \( \vec{p} \) and longitudinal momenta \( p^+ \) and \( p^- \), and is annihilated by the infinite tower of oscillators. The significance of this instability is not immediately clear; we will close our eyes to it for now and proceed to look at other states in the spectrum. When we study the superstring, we will often find that there are no tachyons.

The first excited state is the state

\[ |A^l_1\rangle = a^l_{-1}|\vec{p}\rangle. \]  

(21.27)

Its mass is

\[ m_A^2 = 1 + a. \]  

(21.28)
Now we can see why $a = -1$. Here, $\vec{A}$ is a vector field with $D - 2$ components. In $D$ dimensions, a massive vector field has $D - 1$ degrees of freedom; a massless vector has $D - 2$ degrees of freedom. So $\vec{A}$ must be massless, and $a = 1$ if the theory is Lorentz invariant. Later, we will give a fancier argument for the value of $a$, but the content is equivalent.

At level 2, we have a number of states:

$$\alpha_I^I |\vec{p}\rangle, \alpha_I^{I'} |\vec{p}\rangle. \quad (21.29)$$

These include a vector, a scalar, and a symmetric tensor. We won’t attempt here to group them into representations of the Lorentz group.

It turns out that the value of $D$ is fixed, $D = 26$. In the light cone formulation, the issue is that the light cone theory is not manifestly Lorentz invariant. To establish that the theory is Poincaré invariant, it is necessary to construct the full set of Lorentz generators and carefully check their commutators. This analysis yields the conditions $D = 26$ and $a = -1$. We will discuss the derivation of this result a bit more later. In a manifestly covariant formulation, such as the conformal gauge, the issue is one of unitarity, as in gauge field theories. Decoupling of negative and zero norm states yields, again, the condition $D = 26$.

Turning to the gauge boson, it is natural to ask: what are the fields charged under the gauge symmetry. The answer is suggested by a picture of a meson as a quark and antiquark connected by a string. We can allow the ends of the strings to carry various types of charges. In the case of the bosonic string, these can be, for example, a fundamental and anti-fundamental of $SU(N)$. Then the string itself transforms as a tensor product of vector representations. Because the open strings include massless gauge bosons, this product must lie in the adjoint representation of the group. In the bosonic string theory, one can also have $SO(N)$ and $Sp(N)$ groups. In the case of the superstring, we will see that the group structure is highly restricted. The theory will make sense only in flat ten dimensions, and then only if the group is $O(32)$.

### 21.2 Closed strings

We have begun with open strings, since these are in some ways simplest, but theories of open strings by themselves are incomplete. There are always processes which will produce closed strings. For closed strings, we again have a set of fields $X^I(\sigma, \tau)$. Their action is identical to that we wrote before. But they now obey the boundary conditions:

$$X^I(\sigma + \pi, \tau) = X^I(\sigma, \tau). \quad (21.30)$$
Again, we can write a mode expansion:

\[ X^I = x^I + p^I \tau + \frac{i}{2} \sum_{n \neq 0} \frac{1}{n} (\alpha_n^I e^{-2in(\tau - \sigma)} + \tilde{\alpha}_n^I e^{-2in(\tau + \sigma)}) \]  

(21.31)

The exponential terms are the familiar solutions to the two-dimensional wave equation. One can speak of modes moving to the left ("left movers") and to the right ("right movers") on the string. Again we have commutation relations:

\[ [x^I, p^J] = i \delta^{IJ} \quad [\alpha_n^I, \alpha_n^J] = n \delta_{n+n'}^{IJ} \quad [\tilde{\alpha}_n^I, \tilde{\alpha}_n^J] = n \delta_{n+n'}^{IJ} \]  

(21.32)

Now the Hamiltonian is:

\[ H = \vec{p}^2 + N + \tilde{N} + b \]  

(21.33)

where

\[ N = \sum_{n=1}^{\infty} \alpha_{-n}^I \alpha_n^I \quad \tilde{N} = \sum_{n=1}^{\infty} \tilde{\alpha}_{-n}^I \tilde{\alpha}_n^I. \]  

(21.34)

In working out the spectrum, there is an important constraint. There should be no special point on the string, i.e. translations in the \( \sigma \) direction should leave states alone. The generator of constant shifts of \( \sigma \) can be found by the Noether procedure:

\[ \mathcal{P}_\sigma = \int d\sigma \partial_\tau X^I \partial_\sigma X^I = N - \tilde{N}. \]  

(21.35)

So we need to impose the condition \( N = \tilde{N} \) on the states.

Once more, the lowest state is a scalar,

\[ |T\rangle = |\vec{p}\rangle \quad m_T^2 = b. \]  

(21.36)

Because of the constraint, the first excited state is:

\[ |\Psi_{IJ}\rangle = \tilde{\alpha}_{-1}^I \alpha_{-1}^J |\vec{p}\rangle. \]  

(21.37)

We can immediately decompose these states into irreducible representations of the little group; there is a symmetric traceless tensor; a scalar (the trace); and an antisymmetric tensor. A symmetric, traceless tensor should have, if massive, \( D^2 - D - 1 \) states. Here, however, we have only \( D^2 - 3D + 1 \) states. This is precisely the correct number of states for a massless, spin-two particle – a graviton. The remaining states are precisely the number for a massless antisymmetric tensor field and a scalar. So we learn that \( b = -2 \).

This is a remarkable result. General arguments, going back to Feynman, Weinberg and others, show that a massless spin-two particle, in a relativistic theory, necessarily couples like a graviton in Einstein’s theory. So string theory is a theory
of general relativity. This bosonic string is clearly unrealistic. But the presence of
the graviton will be a feature of all string theories, including the more realistic ones.

21.3 String interactions

The light cone formulation is very useful for determining the spectrum of string
theories, but it is somewhat more awkward for the discussion of interactions. As
explained in the introduction, string interactions are determined geometrically, by
the nature of the string world sheet. Actually turning drawings of world sheets
into a practical computational method is surprisingly straightforward. This is most
easily done using the conformal symmetry of the string theory. So we return to the
conformal gauge. There are close similarities between the treatment of both open
and closed strings. We will start with the treatment of closed strings, for which the
Green functions are somewhat simpler. At the end of this chapter we will return to
open strings.

21.3.1 String theory in conformal gauge

In conformal gauge, the action is:

\[
S = \frac{1}{\pi} \int d^2 \sigma \left( (\partial_{\tau} X^\mu)^2 - (\partial_{\sigma} X^\mu)^2 \right).
\]

(21.38)

Introducing the two-dimensional light cone coordinates

\[
\sigma_\pm = \sigma_0 \pm \sigma_1
\]

(21.39)

the flat world sheet metric takes the form

\[
\eta_{+-} = \eta_{-+} = -\frac{1}{2}
\]

(21.40)

and the action can be written:

\[
S = \frac{1}{8\pi} \int d\sigma_+ d\sigma_- \partial_{\sigma_+} X^\mu \partial_{\sigma_-} X^\mu.
\]

(21.41)

At the classical level, this action is invariant under a conformal rescaling of the
coordinates. If we introduce light cone coordinates on the world sheet, then the
action is invariant under the transformations:

\[
\sigma_\pm \rightarrow f_\pm (\sigma_\pm).
\]

(21.42)

Later, we will Wick rotate, and work with complex coordinates; these conformal
transformations will then be the conformal transformations familiar in complex
variable theory. It is well known that by a conformal transformation one can map
the plane into a sphere, for example. In this case, the regions at infinity with incoming or outgoing strings are mapped to points. The creation or destruction of strings at these points is described by local operators in the two-dimensional, world sheet theory. In order to respect the conformal symmetry, these operators must, like the action, be integrals over the world sheet of local dimension-two operators. These operators are known as vertex operators, $V(\sigma, \tau)$.

In conformal gauge, the action also contains Faddeev–Popov ghost terms, associated with fixing the world sheet general coordinate invariance. We will discuss some of their features later. But let’s focus on the fields $X^\mu$ first. If we simply write mode expansions for the fields (taking closed strings, for definiteness)

$$X^\mu = x^\mu + p^\mu \tau + i \sum_{n \neq 0} \frac{1}{n} \left( \alpha_n^\mu e^{-2i n (\tau - \sigma)} + \tilde{\alpha}_n^\mu e^{-2i n (\tau + \sigma)} \right)$$

(21.43)

we will encounter difficulties. The $\alpha^\mu$s will now obey commutation relations:

$$[x^\mu, p^\nu] = ig^{\mu \nu} \quad [\alpha^\mu_n, \alpha^\nu_{n'}] = n \delta_{n+n'} g^{\mu \nu}.$$  

(21.44)

If we proceed naively, the minus sign means from $g^{00}$ that we will have states in the spectrum of negative or zero norm.

The appearance of negative norm states is familiar in gauge field theory. The resolution of the problem, there, is gauge invariance. One can either choose a gauge in which there are no states with negative norm, or one can work in a covariant gauge in which the negative norm states are projected out. In a modern language, this projection is implemented by the BRST procedure. But it is not hard to check that in a covariant gauge, low-order diagrams in QED, for example, give vanishing amplitudes to produce negative or zero norm states (photons with time-like or light-like polarization vectors). In gauge theories, it is precisely the gauge symmetry which accounts for this. In string theory, it is another symmetry, the residual conformal symmetry of the conformal gauge.

In the chapter on general relativity, we learned that differentiation of the matter action with respect to the metric gives the energy-momentum tensor. In Einstein’s theory, differentiating the Einstein term as well gives Einstein’s equations. In the string case, the world sheet metric has no dynamics (the Einstein action in two dimensions is a total derivative), and the Euler–Lagrange equation for $\gamma$ yields the equation that the energy-momentum tensor vanishes. Quantum mechanically, these will be constraint equations. The components of the energy-momentum tensor are:

$$T_{10} = T_{01} = \partial_0 X \cdot \partial_1 X \quad T_{00} = T_{11} = \frac{1}{2} \left( (\partial_0 X)^2 + (\partial_1 X)^2 \right).$$

(21.45)

The energy-momentum tensor is traceless. This is a consequence of conformal invariance; you can show that the trace is the generator of conformal transformations.
In terms of the light cone coordinates, the non-vanishing components of the stress tensor are:

\[
T_{++} = \partial_+ X \cdot \partial_+ X \quad T_{--} = \partial_- X \cdot \partial_- X.
\]  (21.46)

Note that \(T_{+-} = T_{-+} = 0\). Energy-momentum conservation then says:

\[
\partial_- T_{++} = 0 \quad \partial_+ T_{--} = 0.
\]  (21.47)

As a result, any quantity of the form \(f(x^+)T_{++}\) or \(f(x^-)T_{--}\) is also conserved. Integrating over the world sheet, this gives an infinite number of conserved charges.

We want to impose the condition of vanishing stress tensor as a condition on states. There is a problem, however, and this is one way of understanding the origin of the critical dimension, 26. The obstacle is an anomaly, similar to anomalies we encountered in the first part of this text. One can see the problem if one takes the mode expansions for the \(X^\mu\)s and works out the commutators for the \(T\)s. We will show in the next section that

\[
[T_{++}(\sigma), T_{++}(\sigma')] = \frac{i}{24} (26 - D) \delta'''(\sigma - \sigma') + i (T_{++}(\sigma) + T_{++}(\sigma')) \delta'(\sigma - \sigma')
\]  (21.48)

and a similar equation for \(T_{--}\). The first term is clearly an obstruction to imposing the constraint, unless \(D = 26\). The 26 arises from the energy-momentum tensor of the Faddeev–Popov ghosts. Were it not for the ghosts, strings would never make sense quantum mechanically. One can calculate this commutator painstakingly by decomposing in modes. But there are simpler methods, which also provide important insights into string theory, which we develop in the next section.

### 21.4 Conformal invariance

The analysis of conformal invariance is enormously simplified by passing to Euclidean space. Define:

\[
w = \tau + i \sigma \quad \bar{w} = \tau - i \sigma.
\]  (21.49)

The \(w\)s describe a cylinder. Again, in this section \(\alpha' = 2\). This choice will make the coordinate space Green functions for the \(X^\mu\)s very simple. The Euclidean action is now:

\[
S = \frac{1}{8\pi} \int d^2w \, \partial_w X^\mu \partial_{\bar{w}} X^\mu.
\]  (21.50)

In complex coordinates, the non-vanishing components of the energy-momentum tensor are:

\[
T_{ww} = -\partial_w X \cdot \partial_w X \quad T_{\bar{w}\bar{w}} = -\partial_{\bar{w}} X \cdot \partial_{\bar{w}} X.
\]  (21.51)
We saw in the previous section that the string action, in Minkowski coordinates, is invariant under the transformations:

\[ \sigma^+ \to f(\sigma^+) \quad \sigma^- \to g(\sigma^-). \]  

(21.52)

In terms of the complex coordinates, this becomes invariance under the transformations:

\[ w \to f(w) \quad \bar{w} \to f^*(\bar{w}). \]  

(21.53)

These are conformal transformations of the complex variable, and, as a result of this symmetry, we are able to bring all of the machinery of complex analysis to bear on this problem. One particularly useful conformal transformation is the mapping of the cylinder onto the complex plane:

\[ z = e^w \quad \bar{z} = e^{\bar{w}}. \]  

(21.54)

Under this mapping, surfaces of constant \( \tau \) on the cylinder are mapped into circles in the complex plane; \( \tau \to -\infty \) is mapped into the origin, and \( \tau \to \infty \) is mapped to \( \infty \). Surfaces of constant \( \tau \) are mapped into circles.

It is convenient to write our previous expression for \( X^\mu \) in terms of the variable \( z \). First write our previous expressions:

\[ X^\mu = x^\mu + p^\mu \tau + i \sum_{n \neq 0} \frac{1}{n} \left( \alpha_n^\mu e^{-2in(\tau - \sigma)} + \tilde{\alpha}_n^\mu e^{-2in(\tau + \sigma)} \right) \]

\[ = X_L^\mu + X_R^\mu, \]  

(21.55)

where

\[ X_L = \frac{1}{2} x^\mu + \frac{1}{2} p^\mu (\tau - \sigma) + i \sum_{n \neq 0} \frac{1}{n} \alpha_n^\mu e^{-in(\tau - \sigma)} \]  

(21.56)

\[ X_R = \frac{1}{2} x^\mu + \frac{1}{2} p^\mu (\tau + \sigma) + i \sum_{n \neq 0} \frac{1}{n} \alpha_n^\mu e^{-in(\tau + \sigma)}. \]  

(21.57)

\( X_L \) is holomorphic (analytic) in \( z \), \( X_R \) is antiholomorphic:

\[ \partial X_L = -i \alpha_0^\mu z^{-n-1} \quad \partial X_R = -i \tilde{\alpha}_0^\mu \bar{z}^{-n-1}. \]  

(21.58)

where \( \alpha_0^\mu = \tilde{\alpha}_0^\mu = \frac{1}{2} p^\mu \).

Let us evaluate the propagator of the \( x \)s in coordinate space. The \( X \)s are just two-dimensional quantum fields. Their kinetic term, however, is somewhat unconventional. Because we work with units \( \alpha' = 2 \), so the action has a factor of \( 1/8\pi \) out front. Accounting for the extra \( 4\pi \), the coordinate space-propagator is (in Euclidean
space):

\[
\langle X^\mu(\sigma), X^\nu(0) \rangle = 4\pi \delta^{\mu\nu} \int \frac{d^2k}{(2\pi)^2} \frac{e^{i\sigma \cdot k}}{k^2}.
\] (21.59)

This equation is logarithmically divergent in the infrared. We can use this to our advantage, cutting off the integral at scale \( \mu \) and isolating the \( \ln(\mu |z - z'|) \). The logarithmic dependence can be seen almost by inspection of the integral:

\[
\langle X^\mu(z)X^\nu(z') \rangle = 2\delta^{\mu\nu} \ln(|z - z'|) = \ln(z - z') + \ln(\bar{z} - \bar{z}') + \ln(\mu^2).
\] (21.60)

As we will see shortly, the infrared cutoff will drop out of physically interesting quantities, so we will suppress it in the following.

In the covariant formulation, conformal invariance is crucial to the quantum theory of strings. To understand the workings of two-dimensional conformal invariance, we can use techniques of complex variable theory, and the operator product expansion (OPE). We have discussed the operator product expansion previously, in the context of two-dimensional gauge anomalies. It is also important in QCD, in the analysis of various short-distance phenomena. The basic idea is that if one has two operators, \( \mathcal{O}(z_1) \) and \( \mathcal{O}(z_2) \), when \( z_1 \to z_2 \), we have

\[
\mathcal{O}_i(z_1)\mathcal{O}_j(z_2) \to \sum_k C_{ijk}(z_1 - z_2)\mathcal{O}_k(z_1).
\] (21.61)

The coefficients \( C_{ijk} \) are, in general, singular as \( z_1 \to z_2 \). The power follows from dimensional analysis.

To implement this rather abstract statement, one can insert the two operators in a Green function with other operators, located at some distance from \( z_1 \). In other words, one studies:

\[
\langle \mathcal{O}_i(z_1)\mathcal{O}_j(z_2)\Psi(z_3)\Psi(z_4) \rangle.
\] (21.62)

One can contract the operators in \( \mathcal{O}(z_1) \) with those in \( \mathcal{O}(z_2) \), obtaining expressions which are singular as \( z_1 \to z_2 \), or with the other operators, obtaining non-singular expressions. The leading term in the OPE will come from the term with the maximum number of operators at \( z_1 \) contracted with operators at \( z_2 \); less singular operators will arise when we contract fewer operators.

As an example, which will be useful in a moment, consider the product \( \partial X^\mu(z)\partial X^\nu(w) \). If this appears in a Green function, the most singular term as \( z \to w \) will be that where we contract \( \partial X(z) \) with \( \partial X(w) \). The result will be like the insertion of the unit operator at a point, times the singular function \( 1/(z - w)^2 \), so we can write:

\[
\partial X^\mu(z)\partial X^\nu(\omega) \sim \frac{g^{\mu\nu}}{(z - w)^2} + \ldots.
\] (21.63)
A somewhat more non-trivial, and important, set of operator product expansions are provided by the stress tensor and derivatives of $X$:

$$T(z)\partial X^\nu(w) = \partial X^\mu(z) \partial X^\mu(z) \partial X^\nu(w).$$  \hspace{1cm} (21.64)

Now the most singular term arises when we contract the $\partial X(w)$ with one of the $\partial X(z)$ factors in $T(z)$. The other $\partial X(z)$ is left alone; in Green’s functions, it must be contracted with other more far away operators. So we are left with:

$$T(z)\partial X(w) \approx \frac{1}{(z-w)^2} \partial X(w) + \frac{1}{z-w} \partial^2 X(w) + \cdots.$$ \hspace{1cm} (21.65)

Another important set of operators will turn out to be exponentials of $X$:

$$T(z)e^{ip\cdot x} = k^2 (z-w)^2 e^{ik\cdot x} + \cdots.$$ \hspace{1cm} (21.66)

To get some sense of the utility of conformal invariance and OPEs, let’s compute the commutators of the $\alpha^\mu$s. Start with

$$\alpha^\mu_n = \oint \frac{dz}{2\pi} z^n \partial X^\mu,$$ \hspace{1cm} (21.67)

where the contour is taken about the origin. Now use the fact that on the complex plane, time ordering becomes radial ordering, So, for $|z| > |w|$, \hspace{1cm} (21.68)

$$T \langle \partial X^\mu(z) \partial X^\nu(w) \rangle = \langle \partial X^\mu(z) \partial X^\nu(w) \rangle$$

For $|z| < |w|$, \hspace{1cm} (21.69)

$$T \langle \partial X^\mu(z) \partial X^\nu(w) \rangle = \langle \partial X^\nu(w) \partial X^\mu(z) \rangle.$$  \hspace{1cm} (21.69)

Thus we have:

$$[\alpha^\mu_n, \alpha^\nu_m] = \oint \frac{dz}{2\pi} z^m \oint \frac{dw}{2\pi} w^n \oint \frac{dw}{2\pi} \oint \frac{dz}{2\pi} z^m \partial X^\mu(z) \partial X^\nu(w)$$ \hspace{1cm} (21.70)

where the contour can be taken to be a circle about the origin. In the first term, we take $|z| > |w|$. In the second, $|w| > |z|$. Now to evaluate the integral, do, say, the $z$ integral first. For fixed $w$, deform the $z$ contour so that it encircles $z$ (Fig. 21.1). Then

$$[\alpha^\mu_n, \alpha^\nu_m] = \oint \frac{dw}{2\pi} w^n \oint \frac{dz}{2\pi} z^m \frac{1}{(z-w)^2} = m\delta_{m+n}g^{\mu\nu}.$$ \hspace{1cm} (21.70)

Let’s return to the stress tensor. We expect that the stress tensor is the generator of conformal transformations, and that its commutators should contain information about the dimensions of operators. What we have just learned, by example, is that
the operator products of operators encode the commutators. We could show by the Noether procedure that the stress tensor is the generator of conformal transformations. But let’s simply check. Consider the transformation:

$$z \to z + \epsilon(z).$$  \hspace{1cm} (21.71)

We expect that the generator of this transformation is:

$$\oint dz T(z)\epsilon(z).$$  \hspace{1cm} (21.72)

We take the special case of an overall conformal rescaling:

$$\epsilon(z) = \lambda z.$$  \hspace{1cm} (21.73)

Now suppose that we have an operator, \(\mathcal{O}(w)\), and that

$$T(z)\mathcal{O}(w) = \frac{h}{(z-w)^2}\mathcal{O}(w) + \text{less singular.}$$  \hspace{1cm} (21.74)

Then

$$\left[ \frac{1}{2\pi i} \oint T(z)\epsilon(z), \mathcal{O}(w) \right] = \frac{1}{2\pi i} \oint dz \frac{\lambda z h \mathcal{O}(w)}{(z-w)^2} = \lambda h \mathcal{O}(w).$$  \hspace{1cm} (21.75)

This means that under the conformal rescaling, \(\mathcal{O} \to h \mathcal{O}\), just as we expect for an operator of dimension \(h\). As an example, consider \(\mathcal{O} = (\partial)^n X\). This should have
dimension \( n \), and the leading term in its OPE is just of the form of Eq. (21.74), with \( h = n \).

More precisely, an operator is called a primary field of dimension \( d \) if:

\[
T(z)\mathcal{O}(w) = \frac{d\mathcal{O}}{(z-w)^2} + \frac{\partial \mathcal{O}}{z-w}. \tag{21.76}
\]

Note that \( \partial X(z) \) is an example; \( e^{ip \cdot x} \) is another. However, \( (\partial)^n X \) is not, in general, as the \( 1/(z-w) \) term does not have quite the right form. A particularly interesting operator is the stress tensor itself. Naively, this has dimension two, but it is not a primary field. In the operator product expansion, the most singular term arises from the contraction of all of the derivative terms. This is proportional to the unit operator. The first subleading term, where one contracts just one pair of derivatives, gives a piece proportional to the stress tensor itself:

\[
T(z)T(w) = \frac{D}{(z-w)^4} + \frac{1}{(z-w)^2}T(w). \tag{21.77}
\]

When one includes the Faddeev–Popov ghosts, one finds that they give an additional contribution, changing \( D \) to \( D - 26 \).

The algebra of the Fourier modes of \( T \) is known as the Virasoro algebra, and is important both in string theory, conformal field theory, and mathematics. In the string theory, it provides important constraints on states. Define the operators:

\[
L_n = \frac{1}{2\pi i} \oint dz z^{n+1} T(z). \tag{21.78}
\]

In terms of these,

\[
T(z) = \sum_{m=-\infty}^{\infty} \frac{L_m}{z^{m+2}} \tag{21.79}
\]

and similarly for \( \bar{z} \). Because the stress tensor is conserved, we are free to choose any time (radius for the circle). The operator product (21.77) is equivalent to the commutation relations above. Proceeding as we did for the commutators of the \( \alpha \)s, gives:

\[
[L_n, L_m] = (m-n)L_{m+n} + \frac{D}{12}(m^3 - m)\delta_{m+n}. \tag{21.80}
\]

Using expression (21.16) we can construct the \( L_n \)s:

\[
L_m = \frac{1}{2} \sum :\alpha_{m-n}^\mu \alpha_\mu n : \quad \bar{L}_m = \frac{1}{2} \sum :\bar{\alpha}_{m-n}^\mu \bar{\alpha}_\mu n :. \tag{21.81}
\]

The colons indicates normal ordering. Only when \( m = 0 \) is this significant. In this case, we have to allow for the possibility of a normal ordering constant.
This constant is related to the constant we found in the Hamiltonian in light cone gauge.

\[ L_0 = \sum_{n=0}^{\infty} \alpha_{-n}^{\mu} \alpha_{n}^{\mu} - a \quad \tilde{L}_0 = \sum_{n=0}^{\infty} \tilde{\alpha}_{-n}^{\mu} \tilde{\alpha}_{n}^{\mu} - a. \] (21.82)

Now we want to consider the constraint on states corresponding to the classical vanishing of the stress tensor. Because of the commutation relations, we cannot require all of the \(L_s\)s annihilate physical states. We require instead:

\[ L_m |\psi\rangle = 0 \] (21.83)

for \(m \geq 0\). Since \(L_m^\dagger = L_{-m}\), this insure that

\[ \langle \psi | L_n |\psi\rangle = 0 \quad \forall \ n. \] (21.84)

Because of the constraint \(L_0 = \tilde{L}_0\), at the first excited level, we have the state:

\[ |\epsilon\rangle = \epsilon_{\mu\nu} \alpha_{-1}^{\mu} \tilde{\alpha}_{-1}^{\nu} |p^{\nu}\rangle. \] (21.85)

The \(L_n\), for \(n > 1\), trivially annihilate the state. For \(n = 1\) we have:

\[ L_1 |\epsilon\rangle = \alpha_{0}^{\mu} \epsilon_{\mu\nu} |p^{\nu}\rangle. \] (21.86)

Taking into account also \(\tilde{L}_1\), we have the conditions:

\[ p_{\mu} \epsilon^{\mu\nu} = 0 = p_{\nu} \epsilon^{\mu\nu}. \] (21.87)

This is similar to the condition \(k_{\mu} \epsilon^{\mu}\) familiar in covariant gauge electrodynamics and eliminates the negative norm states. Consider, now, \(L_0\):

\[ L_0 |\epsilon\rangle = (p^2 - a + 1)|\epsilon\rangle. \] (21.88)

So if \(a = 1\), the constraint is \(p^2 = 0\), as we expect from Lorentz invariance. For open strings there is an analogous construction.

### 21.5 Vertex operators and the S-matrix

We have argued that, when the cylinder is mapped to the plane, the creation or destruction of states is described by local operators, known as vertex operators. In this section, we discuss the properties of these operators and their construction. We explain how the space-time S-matrix is obtained from correlation functions of these operators, and compute a famous example.
21.5 Vertex operators and the S-matrix

21.5.1 Vertex operators

There is a close correspondence between states and operators: \( z \to 0 \) corresponds to \( t \to -\infty \). So consider, for example,

\[
\partial_z X^\mu |0\rangle, \tag{21.89}
\]
as \( z \to 0 \). This is:

\[
\partial_z X(z \to 0) |0\rangle = -i \sum_{m=-1}^{\infty} \alpha^\mu_m z^{m+1} |0\rangle. \tag{21.90}
\]

All but the term \( m = -1 \) annihilate the state to the right. Combining this with a similar left-moving operator creates a single particle state.

More generally, in conformal field theories, there is a one to one correspondence between states and operators. This is the realization of the picture discussed in the introduction. By mapping the string world sheet to the plane, the incoming/outgoing states have been mapped to points, and the production or annihilation of particles at these points is described by local operators.

The construction of the \( S \)-matrix in string theory relies on this connection of states and operators. The operators which create and annihilate states are known as vertex operators. What properties should a vertex operator possess? The production of the particle should be represented as an integral over the string world sheet (so that there is no special point along the string). The expression

\[
\int d^2z V(z, \bar{z}) \tag{21.91}
\]

should be invariant under conformal transformations. This means that the operator should possess dimension two; more precisely, it should possess dimension one with respect to both the left- and the right-moving stress tensors:

\[
T(z)V(w, \bar{w}) = \frac{1}{(z-w)^2} V(w, \bar{w}) + \frac{1}{z-w} \partial_w V(w, \bar{w}) + \cdots \tag{21.92}
\]

and similarly for \( \bar{T} \). An operator with this property is called a \((1,1)\) operator.

A particularly important operator in two-dimensional free field theory (i.e. the string theories we are describing up to now) is constructed from the exponential of the scalar field:

\[
\mathcal{O}_p = e^{ip \cdot x}. \tag{21.93}
\]

This has dimension

\[
d = p^2 \tag{21.94}
\]
with respect to the left-moving stress tensor, and similarly for the right-moving part.

With these ingredients, we can construct operators of dimension (1, 1). These are in one to one correspondence with the states we have found in the light cone construction.

(1) The tachyon:

$$e^{lp} \cdot x p^2 = 1.$$  \hfill (21.95)

(2) The graviton, antisymmetric tensor, and dilaton:

$$\epsilon_{\mu\nu} \partial X^\mu \tilde{\partial} X^\nu e^{lp} \cdot x p^2 = 0.$$  \hfill (21.96)

The operator product

$$\partial X^\rho(z) \partial X^\rho(w) \epsilon_{\mu\nu}(p) \tilde{\partial} X^\mu(w) \tilde{\partial} X^\nu(w) e^{lp} \cdot x (w)$$  \hfill (21.97)

contains terms which go as $1/(z - w)^3$ from contracting one of the derivatives in the stress tensor with $e^{lp}$ and one with $\partial X^\mu$. Examining Eq. (21.92), this leads to the requirement

$$p^\mu \epsilon_{\mu\nu}(p) = 0$$  \hfill (21.98)

which we expect for massless spin-2 states. In our earlier operator discussion, this was one of the Virasoro conditions.

(3) Massive states:

$$\epsilon_{\mu_1 \cdots \mu_n}(p) \partial X^{\mu_1} \partial X^{\mu_2} \cdots \partial X^{\mu_n} e^{lp} \cdot x p^2 = 1 - n.$$  \hfill (21.99)

Obtaining the correct OPE with the stress tensor now gives a set of constraints on the polarization tensor; again these are just the Virasoro constraints. Without worrying about degeneracies, we have a formula for the masses:

$$M_n^2 = n - 1.$$  \hfill (21.100)

This is what we found in the light cone gauge. Traditionally, the states were organized in terms of their spins. States of a given spin all lie on straight lines, known as “Regge trajectories.” These results are all in agreement with the light cone spectra we found earlier.

### 21.5.2 The S-matrix

Now we will make a guess as to how to construct an S-matrix. Our vertex operators, integrated over the world sheet, are invariant under reparameterizations and conformal transformation of the world sheet coordinates. We have seen that they correspond to creation and annihilation of states in the far past and far future. We
will normalize the vertex operators so that:

\[ V_i(z)V_j(w) \sim \frac{1}{|z - w|^4}. \]  

So we study correlation functions of the form:

\[ \int d^2z_1 \ldots d^2z_n \langle V_1(z_1, p_1) \ldots V_n(z_n p_n) \rangle. \]

We will include a coupling constant, \( g \), with each vertex operator.

Before evaluating this expression in special cases, let’s consider the problem of evaluating correlation functions of exponentials:

\[ \langle e^{i \sum p_i \cdot X(z_i)} \rangle. \]

An easy way to evaluate this expression is to work in the path integral framework. Then the exponential has the structure

\[ \int d^2z J_{\mu}(z) X(z), \]

where

\[ J_{\mu}(z) = \sum_i p_i \delta^2(z - z_i). \]

But we know that the result of such a path integral is:

\[ \exp \left( i \int d^2z d^2z' J_{\mu}(z) J_{\mu}(z') \Delta(z - z') \right) = \exp \left( \sum p_i \cdot p_j \ln |(z_i - z_j)|^2 \mu^2 \right), \]

where we have made a point of restoring the infrared cutoff.

Let’s consider the infrared cutoff first. Overall, we have a factor:

\[ \mu^{(\sum p_i)^2}. \]

This vanishes as \( \mu \to 0 \), unless \( \sum p_i = 0 \), i.e. unless momentum is conserved. This result is related to the Mermin–Wagner–Coleman theorem that there is no spontaneous breaking of global symmetries in two dimensions. Translational invariance is a global symmetry of the two-dimensional field theory; \( e^{ip \cdot x} \) transforms under the symmetry. The only non-vanishing correlation functions are translationally invariant.

This correlation function also has an ultraviolet problem, coming from the \( i = j \) terms in the sum. Eliminating these corresponds to normal ordering the vertex operators, and we will do this in what follows (we can, if we like, introduce an explicit ultraviolet cutoff; this gives a factor which can be absorbed into the definition of the vertex operators).
There is one more set of divergences we need to deal with. These are associated with a part of the conformal invariance we have not yet fixed. The operators $L_0$, $L_1$ and $L_{-1}$ form a closed algebra. On the plane, they generate overall rescalings ($L_0$), translations ($L_1$) and more general transformations ($L_{-1}$) which can be unified in $SL(2, C)$, the Möbius group. It acts on the world sheet coordinates as:

$$z = \frac{\alpha z' + \beta}{\gamma z' + \delta}. \quad (21.108)$$

These have the feature that they map the plane once into itself. It is necessary to fix this symmetry and divide by the volume of the corresponding gauge group. We can choose the location of three of the vertex operators, say $z_1, z_2, z_3$. These are conventionally taken to be 0, 1, $\infty$. It is necessary also to divide by the volume of this group; the corresponding factor is

$$\Omega_M = |z_1 - z_2|^2 |z_1 - z_3|^2 |z_2 - z_3|^2. \quad (21.109)$$

One can simply accept that this emerges from a Faddeev–Popov condition, or derive this following the exercises at the end of the chapter. Finally, it is necessary to divide by $g_s^2$. This insures that a three-particle process is proportional to $g_s$, a four particle amplitude to $g_s^2$, and so on.

Using these results we can construct particular scattering amplitudes. While physically somewhat uninteresting, the easiest to examine is simply the scattering of tachyons. Let’s specialize to the case of two incoming, two outgoing particles. Putting together our results above we have (remembering that $z_3 \to \infty$):

$$A = \frac{1}{\Omega_M} \int d^2 z_4 |z_1 - z_2|^2 |z_1 - z_3|^2 |z_2 - z_3|^2 |z_3|^{p_4 \cdot (p_1 + p_2 + p_3)} |z_1 - z_2|^{p_1 \cdot p_2} |z_4|^{p_4 \cdot p_1} |z_4 - 1|^{p_4 \cdot p_2}. \quad (21.110)$$

Using momentum conservation, the $z_4$ independent pieces cancel out in the limit, and we are left with:

$$A = \int d^2 z |z|^{2p_1 \cdot p_4} |z - 1|^{2p_2 \cdot p_4}. \quad (21.111)$$

Now we need an integral table:

$$I = \int |z|^{-A} |1 - z|^{-B} d^2 z \quad (21.112)$$

$$= B \left( 1 - \frac{A}{2}, 1 - \frac{B}{2}, \frac{A + B}{2} - 1 \right).$$

Here $B$ is:

$$B = \pi \frac{\Gamma(a)\Gamma(b)\Gamma(c)}{\Gamma(a + b)\Gamma(b + c)\Gamma(c + a)}. \quad (21.113)$$
We can express this result in terms of the Mandelstam invariants for $2 \rightarrow 2$ scattering, $s = -(p_1 + p_2)^2$, $t = -(p_2 - p_3)^2$, and $u = -(p_1 - p_4)^2$. Using the mass shell conditions,

$$p_4 \cdot p_1 = \frac{1}{2} (u + (p_1^2 - p_4^2)) \quad p_4 \cdot p_2 = -(p_3 + p_2 + p_1) \cdot p_2 = \frac{1}{2} (-s - t + 2m^2),$$

(21.114)
gives

$$\mathcal{A} = \frac{\kappa^2}{4\pi} B(-4s + 1, -4t + 1, -4u + 1).$$

(21.115)

This is the Virasoro–Shapiro amplitude. There are a number of interesting features of this amplitude. It has singularities at precisely the locations of the masses of the string states. It should be noted, also, that we have obtained this result by an analytic continuation. The original integral is only convergent for a range of momenta, corresponding, essentially, to sitting “below” the threshold for the tachyon in the intermediate states.

We will not develop the machinery of open string amplitudes here, but it is similar. One again needs to compute correlation functions of vertex operators. The vertex operators are somewhat different. Also, the boundary conditions for the two-dimensional fields, and thus the Green functions, are also different. The scattering amplitude for open string tachyons is known as the Veneziano formula.

### 21.5.3 Factorization

The appearance of poles in the $S$-matrix at the masses of the string states is no accident. We can understand it in terms of our vertex operator and OPE analysis. Suppose that particles one and two, with momenta $p_1$ and $p_2$, have $s = (p_1 + p_2)^2 = -m_n^2$, the mass-squared of one of the physical states of the system. Consider the OPE of their vertex operators:

$$e^{ip_1 \cdot X(z_1)} e^{ip_2 \cdot X(z_2)} \approx e^{i(p_1 + p_2) \cdot X(z_2)} |z_1 - z_2|^2 p_1 \cdot p_2.$$  

(21.116)

So in the $S$-matrix, fixing $z_2 = 0, z_3 = 1$, and $z_4 = \infty$, we encounter:

$$\int d^2z |z_1|^{2p_1 \cdot p_2} e^{i(p_1 + p_2) \cdot X(z_2)} e^{ip_3 \cdot X(z_3)} e^{ip_4 \cdot X(z_4)}.$$  

(21.117)

Using momentum conservation and the on-shell conditions for $p_1$ and $p_2$:

$$2p_2 \cdot p_1 = q^2 - 8$$  

(21.118)
where \( q = p_1 + p_2 \). So the \( z \) integral gives a pole,

\[
A \sim \frac{1}{4 - q^2}
\]  

(21.119)
i.e. it vanishes when the intermediate state is an on-shell tachyon.

This is general. Poles appear in the scattering amplitude when intermediate states go on-shell. The coefficients are precisely the couplings of the external states to the (nearly) on-shell physical state; this follows from the OPE.

### 21.6 The S-matrix vs. the effective action

The Virasoro–Shapiro and Veneziano amplitudes are beautiful formulas. Analogous formulas for the case of massless particles can be obtained. These are particularly important for the superstring. For many of the questions which interest us, we are not directly interested in the \( S \)-matrix. One feature of the string \( S \)-matrix construction is that it involves on-shell states; the momenta appearing in the exponential factors satisfy \( p^2 = -m^2 \), where \( m \) is the mass of the state. So one cannot calculate, for example, the effective potential for the tachyon, since this requires that all momenta vanish. For massless particles things are better, since \( p = 0 \) is the limiting case of an on-shell process. But the \( S \)-matrix is not precisely the effective action. Instead, given the \( S \)-matrix, it is usually a straightforward matter to determine a low-energy effective action which will reproduce it. At tree level, one just needs to subtract massless particle exchanges. In loops, one must be more careful.

It is particularly easy to extract three-point couplings of massless particles at tree level. One just needs to study an “\( S \)-matrix” for three particles (one can be a bit more careful and study a four-particle amplitude, isolating the coefficient of the massless propagator). From our previous analysis, we need

\[
A = \frac{1}{\Omega_M} \langle V_1(z_1) V_2(z_2) V_3(z_3) \rangle,
\]

where we don’t integrate over the locations of the vertex operators. We are free to take \( z_1 \) and \( z_2 \) arbitrarily close to one another. Then the operator product will involve

\[
V_1(z_1) V_2(z_2) \approx C_{123} \frac{1}{|z_1 - z_2|^2} V_3(z_2).
\]

The final correlation function follows from the normalization of the vertex operators and cancels the Möbius volume. So the net result is that \( g_s C_{123} \) is the coupling.

As an example, consider the coupling of two gravitons in the bosonic string. The vertex operator is

\[
V_1 = \epsilon_{\mu\nu}(k_1) \partial X^\mu(z) \bar{\partial} X^\nu(z) e^{ik_1 \cdot X(z)},
\]

(21.122)
and similarly for $V_2$ and $V_3$. So the operator product has the structure:

$$V_1(z)V_2(w) = \frac{1}{|z - w|^4} + \epsilon_{\mu \nu}(k_1)\epsilon_{\rho \sigma}(k_2)e^{i(k_1 + k_2)X(z)}\left( k_1^\nu k_2^\sigma |z - w|^2 \partial X^\mu(z)\bar{\partial}X^n(z) + \cdots \right). \quad (21.123)$$

Here the first term arises from the contraction of all of the $\partial X$ terms with each other. Loosely speaking, it is related to the production of off-shell tachyons. We will ignore it. The second term that we have indicated explicitly comes from contracting the first $\bar{\partial}X$ factor with the second exponential, and the second $\partial X$ factor with the first exponential. The dots indicate a long set of contractions. The complete vertex is precisely the on-shell coupling of three gravitons in Einstein’s theory, along with couplings to the antisymmetric tensor and dilaton. We will not worry with the details here. When we discuss the heterotic string, we will show that the theory completely reproduces the Yang–Mills vertex in much the same way. We shouldn’t be surprised that it is difficult to define off-shell Green functions. In gravity, apart from the $S$-matrix, it is hard to define generally coordinate-invariant observables.

### 21.7 Loop amplitudes

So far, we have considered tree amplitudes. Closed or open strings interact by splitting and joining. Once we allow for quantum fluctuations, strings in intermediate states can split and join. Because of conformal invariance, the only invariant characteristic of these diagrams is their topology (for closed strings, the tree level world sheet has the topology of a sphere). In the closed string case, each additional loop adds a handle to the world sheet. In general, the theory of string loops is complicated. But the description of one-loop diagrams is rather simple, and exposes important features of the theory not apparent in tree diagrams. In the case of closed strings, requiring that the one-loop amplitude be sensible places strong constraints on the theory. Invariance under certain (global) two-dimensional general coordinate transformations, known as modular transformations, will account for many of the features of both the bosonic and superstring theories. In space-time, satisfying these constraints is a necessary condition for the unitarity of the scattering amplitude. In this section, we provide only a brief introduction. We will leave for later the discussion of open string loops.

The one-loop amplitude has the topology of a donut, or torus. A simple representation of a torus is as indicated in Fig. 21.2. In this figure, the world sheet is flat and of finite size. We can think of this torus as living in the complex plane. It is (up to conformal transformations) the world sheet appearing in the Euclidean path integral. The two possible periods of the donut are translated into two complex
The bosonic string

Fig. 21.2. A simple representation of a torus.

periods, \( \lambda_1 \) and \( \lambda_2 \). We require that the fields are periodic under

\[
z \approx z + m\lambda_1 + n\lambda_2.
\]  

(21.124)

We can transform \( \lambda_1 \) and \( \lambda_2 \) by a transformation in the “modular group,” \( SL(2, \mathbb{Z}) \):

\[
\begin{pmatrix}
\lambda_1' \\
\lambda_2'
\end{pmatrix} =
\begin{pmatrix}
a & b \\
c & d
\end{pmatrix}
\begin{pmatrix}
\lambda_1 \\
\lambda_2
\end{pmatrix}
\]  

(21.125)

with \( a, b, c \) and \( d \) integers satisfying \( ad - bc = 1 \), provided we also transform the integers \( n \) and \( m \) by the inverse matrix:

\[
\begin{pmatrix}
m \\
n
\end{pmatrix} =
\begin{pmatrix}
d & -b \\
-c & a
\end{pmatrix}
\begin{pmatrix}
m' \\
n'
\end{pmatrix}
\]  

(21.126)

Now rescale \( z \) by \( \lambda_1 \), and call \( \tau = \lambda_2/\lambda_1 \). Then \( z \) has the periodicities 1 and \( \tau \). Under modular transformations, \( \tau \) transforms as:

\[
\tau \rightarrow \frac{a\tau + b}{c\tau + d}.
\]  

(21.127)

The modular transformations are general coordinate transformations of the world sheet theory, but they are not continuously connected to the identity. In order that one-loop string amplitudes make sense, we require that they are invariant under this transformation. The general amplitude will be a correlation function

\[
\langle V(z_1)V(z_2)\ldots \rangle_{\text{torus}}
\]  

evaluated on the torus. The simplest amplitude is that with no vertex operators inserted. (At tree level, this amplitude vanishes owing to the division by the infinite Möbius volume.) For the bosonic string, we can evaluate the amplitude in light cone gauge. We simply need to evaluate the functional determinant. As these are free fields on a flat space, this is not too difficult. It is helpful to remember some basic field theory facts. The path integral, with initial configuration \( \phi_i(x) \) and final
configuration \( \phi_i(x) \) computes the quantum mechanical matrix element:

\[
\langle \phi_i | e^{-iHT} | \phi_i \rangle. \tag{21.129}
\]

If we take the time to be Euclidean, impose periodic boundary conditions, and sum (integrate) over all possible \( \phi_i \), we have computed:

\[
\text{Tr } e^{-HT} \tag{21.130}
\]

i.e. the quantum mechanical partition function. As described in Appendix C, this observation is the basis of the standard treatments of finite temperature phenomena in quantum field theory. In the present case, the periodicity is in the \( \tau \) direction. So we compute

\[
\text{Tr } e^{-H_{l.c} \tau}. \tag{21.131}
\]

It is convenient to rewrite the light cone Hamiltonian, \( H_{l.c} \), in terms of \( L_0 \) and \( \bar{L}_0 \).

Introducing

\[
q = e^{2\pi i \tau} \quad \bar{q} = e^{-2\pi i \bar{\tau}} \tag{21.132}
\]

we want to evaluate:

\[
\text{Tr } q^{L_0} \bar{q}^{\bar{L}_0}. \tag{21.133}
\]

From any one oscillator with oscillator number \( n \), just as in quantum mechanics, we obtain \((1 - q^n)^{-1}\); so allowing for the different values of \( n \) and the \( D - 2 \) transverse directions, we have:

\[
\prod q^{D/24} \bar{q}^{D/24} (1 - q^n)^{2-D} (1 - \bar{q}^n)^{2-D}. \tag{21.134}
\]

This is conveniently expressed in terms of a standard function, the Dedekind \( \eta \) function:

\[
\eta(q) = q^{1/24} \prod_{n=1}^{\infty} (1 - q^n). \tag{21.135}
\]

We also need the contribution of the zero modes. This is:

\[
\int \frac{d^{D-2}p}{(2\pi)^{D-2}} e^{-\tau_2 p^2} \propto \tau_2^{D-2}. \tag{21.136}
\]

In the final expression, we need to integrate over \( \tau \). The measure for this can be derived from the Faddeev–Popov ghost procedure, but it can be guessed from the requirement of modular invariance. It is easy to check that

\[
\int \frac{d^2\tau}{\tau_2^2} \tag{21.137}
\]
is invariant. So, in 26 dimensions, we finally have

$$Z \propto \int \frac{d^2 \tau}{\tau_2} \tau_2^{-12} |\eta(\tau)|^{-48}. \quad (21.138)$$

Now to check that this is modular invariant, we note, first, that the full modular group is generated by the transformations:

$$\tau \to \tau + 1 \quad \tau \to -1/\tau. \quad (21.139)$$

Under these transformations, as we said, the measure is invariant. The $\eta$ function transforms as:

$$\eta(\tau + 1) = e^{i\pi/12} \eta(\tau) \quad \eta(-1/\tau) = (-i\tau)^{1/2} \eta(\tau) \quad (21.140)$$

Since $\tau_2 \to \tau_2/\tau_1^2 + \tau_2^2$, under $\tau \to -1/\tau$, $Z$ is invariant. Here we see that the bosonic string makes sense only in 26 dimensions.

**Suggested reading**

More detail on the material in this chapter can be found in Green *et al.* (1987) and in Polchinski (1998). The light cone treatment described here is nicely developed in Peskin (1985).

**Exercises**

1. Enumerate the states of the bosonic closed string at the first level with positive mass-squared. Don’t worry about organizing them into irreducible representations, but list their spins.
2. OPEs: explain why $X^\mu$ and $X^\nu$ do not have a sensible operator product expansion. Work out the OPE of $\partial X^\mu$ and $\partial X^\nu$ as in the text. Verify the commutator of $\alpha^\mu$ and $\alpha^\nu$ as in the text.
3. Work out the Virasoro algebra, starting with the operator product expansion for the stress tensor, and using the contour method.
4. Mermin–Wagner–Coleman Theorem: consider a free two-dimensional quantum field theory with a single, massless, complex field, $\phi$. Describe the conserved $U(1)$ symmetry. Show that correlation functions of the form

$$\langle e^{i q_1 \phi(x_1)} \ldots e^{i q_n \phi(x_n)} \rangle \quad (21.141)$$

are non-vanishing only if $\sum q_i = 0$. Argue that this means that the global symmetry is not broken. From this construct an argument that global symmetries are never broken in two dimensions.
5. Show that $\Omega_M$ of Eq. (21.109) is invariant under the Möbius group. You might want to proceed by analogy to the Faddeev–Popov procedure in gauge theories.
(6) Show that the factorization of tree-level $S$-matrix elements is general, i.e. that if the
kinematics are correctly chosen for two incoming particles, 1 and 2, so that $(p_1 + p_2)^2 \approx m_n^2$, so that the amplitude is approximately a product of the coupling of particles 1 and 2 to $n$, times a nearly on-shell propagator for the field $n$. 
The theories we have described were motivated by thinking of a picture of a string moving in space-time. We arrived in this way at a description of strings in terms of two-dimensional quantum fields. The theories, so far, are theories of bosons only. But in this more abstract picture, we can imagine adding two-dimensional fermionic fields as well. This possibility was first considered by Ramond, Neveu and Schwarz, and leads to the superstring theories: Type I, Type IIA and Type IIB, and the two heterotic string theories. We first develop the theories in light cone gauge, where their spectra are readily exhibited. Then we discuss interactions.

### 22.1 Open superstrings

A priori, there appears to be a great deal of freedom in how we introduce fermions: their number, their representations under the (space-time) Lorentz group, and possibly other options. Various consistency conditions restrict these choices. In the case of open strings, we have to introduce one fermion, \( \psi^I \), for each coordinate, \( X^I \). For the action of the fermions we take:

\[
S_\psi = \frac{1}{2\pi} \int d^2 \sigma i \bar{\psi}^I \partial^\alpha \gamma^\alpha \psi^I. \quad (22.1)
\]

In two dimensions, a particularly simple choice for the \( \gamma \)-matrices is:

\[
\gamma^0 = \sigma_2 \quad \gamma^1 = i\sigma_1 \quad (22.2)
\]

and the analog of \( \gamma_5 \) in four dimensions is

\[
\gamma_3 = \sigma_3. \quad (22.3)
\]

The Dirac equation, in this basis, is purely imaginary, so we can take the fermions to be real (Majorana). We can work with eigenfunctions of \( \sigma_3 \):

\[
\psi^I = \begin{pmatrix} \psi^I_- \\ \psi^I_+ \end{pmatrix}. \quad (22.4)
\]
In this way, if we again introduce light cone coordinates on the world sheet,
\[
\sigma^\pm = \tau \pm \sigma \tag{22.5}
\]
the action becomes:
\[
S_\psi = \frac{1}{2\pi} \int d^2\sigma (\psi_+^I \partial_- \psi_+^I + \psi_-^I \partial_+ \psi_-^I). \tag{22.6}
\]

We need to impose boundary conditions at the string end points. To determine suitable boundary conditions, we vary the Lagrangian to obtain the Euler–Lagrange equations. The surface terms which arise in the variation involve \(\psi_+ \delta \psi_+ - \psi_- \delta \psi_-\). So the boundary terms vanish if \(\psi_+ = \pm \psi_-\). An overall sign doesn't matter, so we can take the + sign at \(\sigma = 0\):
\[
\psi_+^I(0, \tau) = \psi_-^I(0, \tau) \tag{22.7}
\]
This leaves two choices for the boundary conditions at \(\sigma = \pi\):
\[
\psi_+^I(\pi, \tau) = \pm \psi_-^I(\pi, \tau). \tag{22.8}
\]

Fermions which obey the boundary condition with the + sign are called Ramond fermions; those with the − sign are called Neveu–Schwarz (NS) fermions. Corresponding to the Ramond case are the mode expansions:
\[
\psi_-^I = \frac{1}{\sqrt{2}} \sum_{n \in \mathbb{Z}} d_n^I e^{-in(\tau - \sigma)} \quad \psi_+^I = \frac{1}{\sqrt{2}} \sum_{n \in \mathbb{Z}} d_n^I e^{-in(\tau + \sigma)}. \tag{22.9}
\]
In the NS case we have:
\[
\psi_-^I = \frac{1}{\sqrt{2}} \sum_{r \in \mathbb{Z} + \frac{1}{2}} b_r^I e^{-ir(\tau - \sigma)} \quad \psi_+^I = \frac{1}{\sqrt{2}} \sum_{r \in \mathbb{Z} + \frac{1}{2}} b_r^I e^{-ir(\tau - \sigma)}. \tag{22.10}
\]

Now we quantize these fields:
\[
\{\psi^I(\sigma, \tau)_\pm, \psi^J(\sigma', \tau)_\pm\} = \pi \delta(\sigma - \sigma') \delta_\pm\delta_{IJ} \tag{22.11}
\]
This gives, for the modes:
\[
\{b_r^I, b_s^J\} = \delta_{IJ} \delta_{r+s} \quad \{d_m^I, d_n^J\} = \delta_{IJ} \delta_{m+n} \tag{22.12}
\]
The Hamiltonian in light cone gauge, for the Ramond sector, is:
\[
H = \vec{p}^2 + N_\alpha + N_d. \tag{22.13}
\]
Here the \(N_s\) are the various number operators:
\[
N_\alpha = \sum_{m=1}^{\infty} \alpha_{-m} \cdot \alpha_m \quad N_d = \sum_{m=1}^{\infty} m d_{-m} \cdot d_m. \tag{22.14}
\]
For the NS sector, \( N_d \) is replaced by \( N_b \):

\[
N_b = \sum_{r=1/2}^{\infty} mb_{-r} b_r. \tag{22.15}
\]

Each of these Hamiltonians has a normal ordering constant. We will determine these shortly. The states of the theory are the eigenstates of the fermion number operators \( b_n^\dagger b_n \), \( d_n^\dagger d_n \), etc., for non-zero \( n \). The eigenvalues can take the values 0 or 1 in each case. The zero modes, which arise in the Ramond sector, are special. They give rise to space-time fermions.

### 22.2 Quantization in the Ramond sector: the appearance of space-time fermions

Usually, we do field theory at infinite volume, but here we are considering field theory at a finite volume \( 0 < \sigma < \pi \), and this has introduced some new features. For the bosonic fields, \( X^I \), we have already seen that there are zero modes, which gave rise to the coordinates and momenta of space-time. For the fermions, we now have the new feature that there are two sectors, with two independent Hilbert spaces. It is tempting to simply keep one, but it turns out that when we consider string interactions, it is necessary to include both: even if we attempt to exclude, say, the Ramond states, they will appear in string loop diagrams.

There is another feature: the appearance of fermion zero modes \( (d_I^0) \) in the Ramond sector. These are not conventional creation and annihilation operators. They obey the commutation relations:

\[
\{ d_I^0, d_J^0 \} = \delta^{IJ}. \tag{22.16}
\]

These are, up to a factor of 2, the anticommutation relations of Dirac gamma matrices for a \( D - 2 \)-dimensional space, i.e. they are associated with the group \( O(D - 2) \). Anticipating the fact that \( D = 10 \), we are interested in the Dirac matrices of \( O(8) \). Before giving a construction of the spinor representations of \( O(8) \), let us first simply state the basic result: \( O(8) \) has two spinor representations, \( 8_s \) and \( 8_s' \), and a vector representation, \( 8_v \), all 8-dimensional. So we can realize the commutation relations, not on a Fock space, but on one of the 8-dimensional representations of \( O(8) \). Labeling these states \( a, \dot{a} \), then

\[
\langle \dot{a} \left| d_I^0 \right| a \rangle = \frac{1}{\sqrt{2}} \gamma_{a a}^I. \tag{22.17}
\]

We can construct an explicit representation for these matrices in various ways. A simple, and easy to remember construction, is to think of \( O(8) \) as acting on eight
coordinates, \( x^I \). Group these into complex coordinates:
\[
z^1 = x^1 + ix^2 \quad z^2 = x^3 + ix^4 \quad z^3 = x^5 + ix^6 \quad z^4 = x^7 + ix^8
\]
(22.18)
and their complex conjugates. This defines an embedding of \( U(4) \) in \( O(8) \). Correspondingly, we define
\[
a^1 = (d^1_0 + id^2_0),
\]
(22.19)
etc. The \( a^i \)'s obey the commutation relations:
\[
\{a^i, a^{j\dagger}\} = \delta^{ij},
\]
(22.20)
all others vanishing. These are just the conventional anticommutation relations of fermion creation and annihilation operators (but remember for this discussion, these are just matrices, and shouldn’t be confused with the \( d_n \)'s, which are genuinely creation and annihilation operators). Among products of these operators we can distinguish two classes: those built from an even number of \( a \)'s, and those built from an odd number. In four dimensions, the analogous distinction corresponds to the eigenvalue (\( \pm 1 \)) of \( \gamma^5 \).

Now we define a state, \( |0\rangle \), annihilated by the \( a^i \)'s. We can then form two sets of states, those with “even fermion number” and those with odd. The even states are:
\[
|0\rangle \quad a^i a^{i\dagger} |0\rangle \quad a^1 a^2 a^3 a^4 |0\rangle.
\]
(22.21)
These states form one of the 8 representations, say \( 8_s \). The second is formed by the states of odd fermion number. States are now labeled \( |p, a, \{\text{oscillators}\}\rangle \).

What we have learned is that the states in the Ramond sector are space-time fermions; the states in the NS sector are space-time bosons.

### 22.3 Type II theory

For closed strings, we still have two-component fields \( \psi \), but the possible choices of boundary conditions are somewhat different. We still require that the fermion surface terms vanish, but we also require that currents such as \( \psi^I \psi^I \) be periodic. (These currents are part of the generators of rotations in space-time.) So we impose Ramond and Neveu–Schwarz boundary conditions independently on the left and right movers. Indeed, we treat the left- and right-moving fermions as independent fields. Recalling that the Lagrangian for the fermions breaks up into left- and right-moving parts. They have the mode expansions:
\[
\psi^I = \sum_{n \in \mathbb{Z}} d^I_n e^{-2in(\tau - \sigma)} \quad \psi^I = \sum_{n \in \mathbb{Z} + 1/2} b^I_n e^{-2ir(\tau - \sigma)}
\]
(22.22)
in the Ramond and NS sectors, respectively, and
\[
\bar{\psi}^I = \sum d^I_n e^{-2in(\tau + \sigma)} \bar{\psi}^I = \sum b^I_n e^{-2ir(\tau + \sigma)}.
\]
(22.23)
The light cone Hamiltonian is now:

\[ H = p^2 + N_\alpha + \bar{N}_\alpha + N_d + \bar{N}_d - a. \] (22.24)

In constructing the spectrum, this must be supplemented with the condition of invariance under shifts in \( \sigma \); in the covariant formulation, this was the \( L_0 = \bar{L}_0 \) constraint.

**22.4 World sheet supersymmetry**

Before considering the spectrum, we consider the question of supersymmetry. The theory we are considering is supersymmetric in two dimensions. Just as we decomposed the fermions into left and right movers, we can introduce a two-component anticommuting parameter \( \theta \):

\[ \theta = \begin{pmatrix} \theta_- \\ \theta_+ \end{pmatrix}. \] (22.25)

Then we define the superfield:

\[ Y^I = X^I + \bar{\theta} \psi^I + \frac{1}{2} \bar{\theta} \theta B^I. \] (22.26)

We will see shortly that \( B^I \) is an auxiliary field, which in the case of strings in flat space, we can set to zero by its equations of motion. The supersymmetry generators are:

\[ Q_A = \frac{\partial}{\partial \bar{\theta}_A} + i (\gamma^\alpha \theta)_A \partial_\alpha \] (22.27)

(we are using the capital letter \( A \) for two-dimensional spinor indices here, to distinguish them from the letter \( a \), which we used for \( O(8) \) spinor indices, and the letter \( \alpha \), which we used for two-dimensional vector indices). As in four dimensions, we can introduce a covariant derivative operator which anticommutes with the supersymmetry generators:

\[ D = \frac{\partial}{\partial \bar{\theta}} - i \gamma^\alpha \theta \partial_\alpha \] (22.28)

In terms of the superfields, the action may be written in a manifestly invariant way:

\[ S = \frac{i}{4\pi} \int d^2 \sigma d^2 \theta \bar{D}Y^\mu D Y_\mu \]

\[ = -\frac{1}{2\pi} \int d^2 \sigma (\partial_\alpha X^I \partial^\alpha X^I - i \bar{\psi}^I \gamma^\alpha \partial_\alpha \psi^I - B^I B^I). \] (22.29)

Note that \( B^I \) vanishes by its equations of motion.

Finally, note that in the NS sectors, the boundary conditions explicitly break the world sheet supersymmetry; they map bosonic fields into fermionic fields,
and vice versa, which obey different boundary conditions. The Ramond sector is supersymmetric.

In the covariant formulation, this supersymmetry is essential to understanding the full set of constraints on the states. But it is important to stress that it is a symmetry of the world sheet theory; its implications for the theory in space-time are subtle.

### 22.5 The spectra of the superstrings

We have, so far, considered the world sheet structure of the superstring theories. We have not yet explored their spectra in detail. As in the case of the bosonic string, we will see that these theories possess a massless graviton. We will also find that they have a massless spin-3/2 particle, the gravitino. Consistent couplings of such a particle require that the space-time theory is supersymmetric.

#### 22.5.1 The normal ordering constants

First, we give a general formula for the normal ordering constant. This is related to the algebra of the energy-momentum tensor we have discussed in Section 21.4. For a left- or right-moving boson, with modes which differ from an integer by $\eta$ (e.g. modes are $1 - \eta$, $2 - \eta$, etc.), the contribution to the normal ordering constant is:

$$\Delta = -\frac{1}{24} + \frac{1}{4} \eta(1 - \eta).$$

(22.30)

For fermions, the contribution is the opposite. So we can recover some familiar results. In the bosonic string, with 24 transverse degrees of freedom, we see that the normal ordering constant is $-1$. For the superstring, in the NS–NS sector, we have a contribution of $-1/24$ for each boson, and $1/24 - 1/16$ for each of the eight fermions on the left (and similarly on the right). So the normal ordering constant is $-1/2$. For the RR sector, the normal ordering vanishes.

There are simple derivations of this formula, whose justification requires careful consideration of conformal field theory. The normal ordering constant is just the vacuum energy of the corresponding two-dimensional free field theory. So we need

$$f(\eta) = \frac{1}{2} \sum_{n=1}^{\infty} (n + \eta).$$

(22.31)

Ignoring the fact that the sum is ill-defined, we can shift $n$ by one, and compensate by a change in $\eta$:

$$f(\eta) = f(\eta + 1) + \frac{1}{2}(1 + \eta).$$

(22.32)
If we assume that the result is quadratic in $\eta$, we recover the formula above, up to the constant. We can “calculate” this constant by the following trick, known as zeta-function regularization. For $\eta = 0$, we need:

$$
\sum_{n=1}^{\infty} n = \lim_{s \to -1} \sum_{n=1}^{\infty} n^{-s}.
$$

(22.33)

The object on the right-hand side of this equation is $\zeta(s)$, the Riemann zeta function. The analytic structure of this function is something of great interest to mathematicians, but one well known fact is that its singularities lie off the real axis. Using integral representations, one can derive a standard result: $\zeta(-1) = -1/12$. This fixes the constant as $-1/24$. This argument may (should) appear questionable to the reader. The real justification comes from considering questions in conformal field theory.

### 22.5.2 The different sectors of the Type II theory

In the Type II theory, there are four possible choices of boundary conditions: NS for both left and right movers, Ramond for both left and right movers, Ramond for left and NS for right and NS for left and R for right. We will refer to these as the NS–NS, R–R, R–NS and NS–R sectors. Consider, first, the NS–NS sector. There are no zero-mode fermions, so we just have a normal (unique) ground state for the oscillators. From our computation of the normal ordering constants in the previous section, we see that $a = -1/2$ for both left and right movers. The lowest state is simply the state $|\vec{p}\rangle$. It has mass-squared $-1$ (in units with $\alpha' = 2$). Since no oscillators are excited, the $L_0 = \tilde{L}_0$ condition is satisfied. Now consider the first excited states. Again, we must have invariance under $\sigma$ translations, so these are the states:

$$
\psi^L_{-1/2} \tilde{\psi}^L_{-1/2} |\vec{p}\rangle.
$$

(22.34)

Because $a = -1/2$ for both left and right movers, these states are massless. The symmetric combination here contains a scalar and a massless spin-two particle, the graviton; the antisymmetric combination is an antisymmetric tensor field. At the next level, we can create massive states using four space-time fermions or two bosons, or one fermion or two bosons.

Let’s turn to the other sectors. Consider, first, the R–NS sector, where $\psi$ is Ramond, $\tilde{\psi}$ is NS. Now, the left-moving normal ordering constant is zero, while the right-moving constant is $-1/2$. So we can satisfy the level-matching condition (invariance under $\sigma$ translations) if we take the left movers to be in their ground state and take the right-moving NS state to be an excitation with a single fermion
operator above the ground state, i.e.:

\[ |\Psi_a^I\rangle = \tilde{\psi}^{-1/2}_{-1/2} |a\tilde{p}\rangle. \tag{22.35} \]

From the space-time viewpoint, these are particles of spin-3/2 and 1/2. In the NS–R sector, we have another spin-3/2 particle.

Just as a massless spin-two particle requires that the underlying theory be generally covariant, a massless spin-3/2 particle, as we discussed in the context of four-dimensional field theories, requires space-time supersymmetry. But now we seem to have a paradox. With space-time supersymmetry, we can’t have tachyons, yet our lowest state in the NS–NS sector, |\tilde{p}\rangle, is a tachyon.

The solution to this paradox was discovered by Gliozzi, Scherk and Olive, who argued that it is necessary to project out states, i.e. to keep only states in the spectrum which satisfy a particular condition. This projection, which yields a consistent supersymmetric theory, is known as the GSO projection. Note, first, that we have been a bit sloppy with the fermion indices on the ground states. We have two types of fermion indices, \( a \) and \( \dot{a} \), corresponding to the two spinor representations of \( O(8) \). So we do the following. We keep only states on the left which are odd under left-moving world sheet fermion number; we do the same on the right, but we include in the definition of world sheet fermion number the chirality of the zero-mode states. We take

\[ (-1)^F = e^{i\pi \gamma^9} \times e^{i\pi \sum_{i=1}^\infty \gamma_a \gamma_{-a}}. \tag{22.36} \]

In the R–NS sector, we make a similar set of projections. Here we have a choice, however, in which chirality we take. If we take the opposite chirality, we get the Type IIA theory; if we take the same chirality, we get the Type IIB theory.

Returning to the NS–NS sector, we make a similar projection, keeping only states which are odd under both left- and right-moving fermion number. In this way we eliminate the would-be tachyon in this sector.

Somewhat more puzzling is the R–R sector in each theory. Here both the left- and right-moving ground states are spinors. So in space-time, the states are bosons. We can organize them as tensors by constructing antisymmetric products of \( \gamma \)-matrices, \( \gamma_{ijk...} \). As we know from our experience in four dimensions, these form irreducible representations, in this case of the little group \( O(8) \). Thinking of our construction of the \( \gamma \)-matrices in terms of the \( a \)s, we can see \( \gamma \)s with even numbers of indices connect states of opposite chirality, while those with odd numbers connect states with the same chirality. Which tensors appear depends on whether we consider the IIA or IIB theories. In the IIA case, only the tensors of even rank are non-vanishing. These tensors correspond to field strengths (one can consider an analogy with the magnetic moment coupling in electrodynamics, \( \bar{\psi} \gamma^{\mu\nu} \psi \)). So in the IIA theory, one has second- and fourth-rank tensors; the sixth- and eighth-rank field strengths are dual to these. In terms of gauge fields, there is a one-index tensor (a vector), and a
third-rank antisymmetric tensor. In the IIB theory, there is a scalar, a second-rank
tensor and a fourth-rank tensor. In string perturbation theory, because the couplings
are through the field strengths, there are no objects carrying the fundamental charge.
Later we will see that there are non-perturbative objects, D-branes, which carry
these charges.

22.5.3 Other possibilities: modular invariance and the GSO projection

The reader may feel that the choices of projections, and for that matter the choices
of representations for the two-dimensional fermions, seem rather arbitrary. It turns
out that the possible choices, at least for flat background space-times, are highly
restricted. There are only a few consistent theories. Those we have described are the
only ones without tachyons, and with both left- and right-moving supersymmetries
on the world sheet.

In the bosonic string theory, we saw that it was crucial that the theory be formu-
lated in 26 dimensions. One of the problems with the theory outside of 26 dimen-
sions was that it is not modular invariant. This means that it is not invariant under cer-
tain global two-dimensional general coordinate transformations. This world sheet
anomaly is correlated with anomalies in space-time. As for the gauge anomalies in
field theories, these lead to breakdown of unitarity, Lorentz invariance, or both.

For the superstring theories, we will now explain why modular invariance de-
mands a projection like the GSO projection. The point is that modular invariance
relates sectors with different choices of boundary condition.

In our discussion of string theories up to this point, path integrals have appeared
occasionally, but they are extremely useful in discussing string perturbation theory.
The propagation of strings can be described by a two-dimensional path integral, with
the string action, in much the same way as the amplitude for the motion of a particle.
At tree level, the closed string world sheet has the topology of a sphere. At one loop,
it has the topology of a torus. So at one loop, string amplitudes can be described
as path integrals of a two-dimensional field theory on a torus. Note that we need,
here, the full path integral, not simply the generator of Green’s function for the field
theory. The path integral on the torus, with no insertion of vertex operators, yields
the partition function of the two-dimensional field theory. To understand this, let’s
consider the fermion partition function. Actually, there are several fermion partition
functions. Let’s begin with a single, right-moving Majorana fermion, and take, first,
Neveu–Schwarz boundary conditions. There are two sorts of partition function we
might define. First:

\[
\text{Tr } q^{L_0} = \prod_{r=1/2}^{\infty} \left( 1 + q^r \right).
\]  

(22.37)
Alternatively, we can evaluate:

\[
\text{Tr} \left( (-1)^F q^{L_0} \right) = \prod_{r=1/2}^{\infty} (1 - q^r). \tag{22.38}
\]

From a path integral point of view, the first expression is like a standard thermal partition function. It can be represented as a path integral with anti-periodic boundary conditions in the time direction. The second integral corresponds to a path integral with even boundary conditions for fermions in the time direction. We can represent the torus as in Fig. 21.2. Taking the vertical direction to be the time direction and the horizontal direction the space direction, we can indicate the boundary conditions with plus and minus signs along the sides of the square. Recalling the action of modular transformations on the torus, however, we see that the modular group mixes up the various boundary conditions. Not only does it mix the temporal boundary conditions, but it mixes the spatial boundary conditions as well.

It will be convenient for much of our later analysis to group the fermions in complex pairs. In the present case, this grouping is rather arbitrary, say \( \Psi^1 = \psi^1 + i \psi^2 \) and so on. Then the partition functions can be conveniently written in terms of \( \theta \) functions. These functions, which have been extensively studied by mathematicians, transform nicely under modular transformations:

\[
\vartheta \begin{bmatrix} \theta \\ \phi \end{bmatrix}(0, \tau) = \eta(\tau)e^{2\pi i \theta} q^{\theta^2/2-1/2} \prod_{m=1}^{\infty} \left[ 1 + e^{2\pi i \phi} q^{m+\theta-1/2} \right] \times \left[ 1 + e^{-2\pi i \phi} q^{m-\theta-1/2} \right]. \tag{22.39}
\]

Under \( \tau \rightarrow \tau + 1 \),

\[
\vartheta \begin{bmatrix} \theta \\ \phi \end{bmatrix}(0, \tau + 1) = e^{i\theta^2-\theta \phi} \vartheta \begin{bmatrix} \theta \\ \phi - \theta \end{bmatrix}(0, \tau) \tag{22.40}
\]

while, under \( \tau \rightarrow -1/\tau \),

\[
\vartheta \begin{bmatrix} \theta \\ \phi \end{bmatrix}(0, 1/\tau) = e^{2\pi i \theta \phi} \vartheta \begin{bmatrix} -\phi \\ \theta \end{bmatrix}(0, \tau). \tag{22.41}
\]

These transformation properties have a physical interpretation. Returning to Eqs. (21.125)–(21.127), the transformation \( \tau \rightarrow -1/\tau \) exchanges the time and space directions of the torus. So these transformations interchange sectors with a given projection (multiplication of states by a phase) with states with a twist in the space direction. This is precisely what one would expect from a path integral, where boundary conditions in the time direction correspond to weighting of states with (symmetry) phases.
Calling

\[ Z_\mu^\alpha(\tau) = \frac{1}{\eta(\tau)} \left[ \frac{\alpha/2}{\beta/2} \right] (0, \tau) \]  

(22.42)

the partition function for the eight fermions in the NS sector is \((Z_0^1)^4\), for example. If we include a \((-1)^F\) factor, this is replaced by \((Z_1^1)^4\). We can work out the similar expressions for the Ramond sector. From our expression for the transformation of the \(\theta\) functions, it is clear that no one of these is modular invariant by itself, as we would expect from our path integral arguments. So it is necessary to combine them, and include also the eight bosons. When we do, we have the possibility of including minus signs (in more general situations, as we will see later, we will have more complicated possible phase choices). There are a finite number of possible choices. Two that work are:

\[ Z_\pm = \frac{1}{2} \left[ Z_0^0(\tau)^4 - Z_1^0(\tau)^4 + Z_0^1(\tau)^4 - Z_1^1(\tau)^4 \right]. \]  

(22.43)

These transform simply under the modular transformations; all of the terms transform to each other, up to an overall factor. There is a similar factor from the left-moving fermions (where one need not, a priori, take the same phase). Recall that the bosonic partition function is

\[ Z_X(\tau) = (4\pi \alpha' \tau_2)^{-1/2} |\eta(q)|^{-2}. \]  

(22.44)

Here the \(\eta\) function comes from the oscillators. The \(\tau_2\) factors come from the integration over the momenta. There are two additional such factors, coming from the integrals over the two light cone momenta. So the full partition function is:

\[ Z = C \int \frac{d^2\tau}{\tau_2^2} Z_X^8 Z^+(\tau) Z^\pm(\tau)^*. \]  

(22.45)

It is not hard to check that this expression is modular invariant.

If we examine the partition function carefully, we see that we have uncovered the GSO projection. Consider the first two terms in \(Z^\pm\). This is just

\[ \text{Tr}(1 - (-1)^F)_{\text{NS}}, \]  

(22.46)

i.e. it says that the physical states of the theory, in the NS sector, are only those of odd fermion number. There is a similar projector in the Ramond sector. The two possible choices of left- relative to right-moving \(Zs\) correspond precisely to the two possible supersymmetric string theories. Our original argument for the GSO projector was consistency in space-time, but here we have a more direct, world sheet consistency argument.
These are the only choices of phases which lead to supersymmetric strings in ten dimensions. However, there are other choices which lead to non-supersymmetric strings. These give the Type 0 superstring. We will leave consideration of these theories to the exercises.

22.5.4 More on the Type I theory: gauge groups

In our discussion of the bosonic string theory, we mentioned that one can obtain non-Abelian gauge groups by allowing charges at the ends of the strings. There are an infinite set of possibilities, which we did not explore, as all of these theories have other problematic features if one is trying to describe Nature.

In the case of open superstrings, it turns out that the possible structures are quite constrained. First, it is necessary to include closed strings as well in order to obtain a unitary theory. This can be seen by considering scattering of four open strings. By stretching the diagram of Fig. 22.1, one can see that closed strings appear in intermediate states. These strings cannot be oriented. This leads to a different structure in the closed string sector than we saw in the IIA or IIB theories. It is necessary to require that states be symmetric under exchange of left- and right-moving quantum numbers. We will discuss the required projection later when we talk about $D$-branes and orientifold planes.

Second, it turns out that absence of anomalies fixes uniquely the gauge symmetry to be $O(32)$. From the point of view of our experience with four-dimensional anomalies, this is somewhat surprising, but it turns out that in ten dimensions supergravity by itself can be anomalous, and this is the case for the open string. Allowing for charges at the end of the string, leads to a set of additional mixed gauge and gravitational anomalies. Almost miraculously, if one takes the ends of the string to lie in the vector representation of $O(32)$, all anomalies cancel.
22.6 Manifest space-time supersymmetry: the Green–Schwarz formalism

In the Ramond–Neveu–Schwarz formalism, space-time supersymmetry is obscure. It only arises after imposing the GSO projector. The supersymmetry operators must connect the different sectors – essentially different two dimensional field theories. These operators can be constructed, though we will not do that in this text. Instead, we consider in this section a different formalism, the Green–Schwarz formalism, in which the space-time supersymmetry is manifest. This formalism is best understood in the light cone gauge.

In the Green–Schwarz formalism, one still has the bosonic coordinates, $X^I$, but the eight fermionic coordinates, $\psi^I$, in the vector representation of $O(8)$, are replaced by eight fermionic coordinates in one of the spinor representations of $O(8)$ (we have already seen that $O(8)$ possesses two spinor representations of opposite chirality). These are usually written as $S^a(\sigma, \tau)$. Their Lagrangian is:

$$L_{gs} = \frac{i}{2\pi} \bar{S}^a \rho^a \partial_\alpha S^a,$$

(22.47)

where we have written the $S$s as two component fermions, and $\rho^a$ denotes the two-dimensional $\gamma$-matrices. The $S_a$s can be taken real (Majorana). They can be decomposed into left and right movers, $S_\pm$. Unlike the case of RNS fermions, both for closed and open strings, one has only one boundary condition. As for the RNS fermions, for open strings, the boundary condition relates the left and right movers:

$$S_+^a(0, \tau) = S_-^a(0, \tau) \quad S_+^a(\pi, \tau) = S_-^a(\pi, \tau).$$

(22.48)

For the closed strings, one simply has periodicity,

$$S_\pm^a(\sigma + \pi, \tau) = S_\pm^a(\sigma, \tau).$$

(22.49)

The mode expansions, in the case of closed strings, are:

$$S_+^a = \sum_{-\infty}^{\infty} S_n^a e^{-2in(\tau - \sigma)}$$

$$S_-^a = \sum_{-\infty}^{\infty} \bar{S}_n^a e^{-2in(\tau + \sigma)}.$$

(22.50)

The $S_n$s obey the anticommutation relations:

$$\{S_n^a, S_m^b\} = \delta^{ab} \delta_{m+n} \quad \{\bar{S}_n^a, \bar{S}_m^b\} = \delta^{ab} \delta_{m+n}.$$

(22.51)

For non-zero $n$ these are canonical fermion creation and annihilation operator anticommutation relations. Because of their quantum numbers, the $S$s, acting on space-time bosonic states, produce fermionic states, and vice versa.
The superstring

The light cone Hamiltonian, in terms of these fields, takes the form:

$$H = \frac{1}{2p^+}((p^I)^2 + N + \tilde{N}),$$

(22.52)

where

$$N = \sum_{m=1}^{\infty} (\alpha_m^I \alpha_m^I + mS_m^a S_m^a) \quad \tilde{N} = \sum_{m=1}^{\infty} (\tilde{\alpha}_m^I \tilde{\alpha}_m^I + m\tilde{S}_m^a \tilde{S}_m^a).$$

(22.53)

Note that there is no normal ordering constant; more precisely, the normal ordering constants associated with the left- and right-moving fields vanish, because the contributions of the bosonic and fermionic fields cancel (as they do in the Ramond sector of the superstring).

As in the Ramond sectors of the superstring theories, the anticommutation relations of the zero modes are important and interesting:

$$\{S_0^a, S_0^b\} = \delta^{ab}.$$  \hspace{1cm} (22.54)

Again they are similar to the anticommutation relations of Dirac $\gamma$-matrices, but now the indices are different than in the RNS case. The solution is to allow $S_0$ to act on sixteen states, eight of which carry spinor labels, $\dot{b}$, and eight of which carry $O(8)$ vector labels, $I$. Then

$$\langle I | S_0^a | \dot{b} \rangle = \gamma_I^{\dot{a}}.$$  \hspace{1cm} (22.55)

We’ll leave the verification of this relation for the exercises, and proceed directly to the identification of the massless states of the closed string theories. The IIA and IIB theories are distinguished by the relative helicities of the $S$ and $\tilde{S}$ fields. In the IIA case, they are opposite; in the IIB case the same. The massless fields are just obtained by tensoring the left and right states of the zero modes. The states

$$\epsilon_{IJ} |I\rangle \times |J\rangle$$  \hspace{1cm} (22.56)

are the graviton, $B$-field and dilaton; the states where $I \to a$ or $J \to a$, are the two gravitini of the theory; those where both $I$ and $J$ are replaced by spinor indices are the states we discovered in the Ramond–Ramond sector of the superstring theories.

In this formalism, the space-time supersymmetry is manifest. There are two types of supersymmetry generators. One generates not only space-time supersymmetries, but world sheet supersymmetries as well. This is as it should be; the world sheet Hamiltonian in the light cone gauge is also the space-time Hamiltonian.

$$Q^{\dot{a}} = \frac{1}{\sqrt{p^+}} \gamma^{\dot{a}, \dot{\alpha}}_+ \sum_{-\infty}^{\infty} S_{-n}^a \alpha_n^I.$$  \hspace{1cm} (22.57)
The second set are built of the zero modes alone:

\[ Q^a = \sqrt{2} P^+ S_0^a. \]  \hspace{1cm} (22.58)

The supersymmetry generators obey the commutation relations:

\[ \{ Q^a, Q^b \} = 2 P^+ \delta^{ab} \]  \hspace{1cm} (22.59)

\[ \{ Q^a, \dot{Q}^b \} = \sqrt{2} \gamma^I a^I P^I. \]  \hspace{1cm} (22.60)

\[ \{ \dot{Q}^a, Q^b \} = 2 H \delta^{ab}. \]  \hspace{1cm} (22.61)

The manifest supersymmetry and the close connection between world sheet and space-time supersymmetries makes the Green–Schwarz formalism a powerful tool, both conceptually and computationally, despite its lack of manifest Lorentz invariance.

### 22.7 Vertex operators

Because there are more world sheet fields in the superstring than in the bosonic string, the vertex operators are more complicated. In the RNS formalism, the supersymmetry on the world sheet is a relic of a larger, local supersymmetry, much as conformal invariance is a relic of the general coordinate invariance of the two-dimensional supersymmetry. The resulting superconformal symmetry provides constraints on vertex operators beyond those of the Virasoro algebra. These constraints can be implemented in a variety of ways, depending on how one treats the superconformal ghosts. In the simplest version, the vertex operators must be supersymmetric. In the case of the Type II theories, the vertex operators must respect both the left- and right-moving supersymmetries. For the massless fields of the Type II theory, for example:

\[ V = \epsilon_{\mu\nu}(\tilde{\partial} X^\mu - i k_\rho \psi^\rho \psi^\mu)(\tilde{\partial} X^\nu - i k_\sigma \tilde{\psi}^\sigma \tilde{\psi}^\nu)e^{ik \cdot x}. \]  \hspace{1cm} (22.62)

Here \( \epsilon \) is subject to the constraint \( k^\mu \epsilon_{\mu\nu} = 0 \). Depending on the symmetries of \( \epsilon \), the vertex operator describes production of gravitons, dilatons, or antisymmetric tensor fields. It is straightforward to check that the coupling of three gravitons is that expected from the Einstein Lagrangian.

In the Green–Schwarz formalism, it is Lorentz invariance which governs the form of the vertex operators. As in the covariant formulation, the vertex operators in the Type II theory are products of separate vertex operators for the left and the right movers, with \( e^{ik \cdot x} \) factors. These have the structure:

\[ V_B = \zeta_{\mu\nu} B^\mu \tilde{B}^\nu e^{ik \cdot x}, \]  \hspace{1cm} (22.63)
The superstring

\[ B^I = \partial X^I - R^{IJ} k^J \quad B^+ = p^+ \quad (22.64) \]

and, from the light cone gauge condition, \( \xi^{\mu+} = 0 \). Here,

\[ R^{IJ} = \frac{1}{4} \gamma^{IJ}_{ab} S^a S^b. \quad (22.65) \]

In the Green–Schwarz approach, it is not more difficult to deal with vertex operators for fermions or for what we have, in the covariant formulation, called the R–R states. The polarizations, \( \zeta_{\mu
u} \), are replaced by polarizations with one or two spinor indices. Then, as appropriate, one replaces the \( B^\mu \)'s with fermionic operators, \( F^a \) and \( \dot{F}^\dot{a} \). We will not give these here as we will not need them in the text, but they can be found in the references. In the covariant approach, more conformal field theory machinery is required to construct fermion emission operators.

Suggested reading

The superstring is well treated in various textbooks. Green et al. (1987) focus heavily on the light cone formulation; Polchinski (1998) focuses on the RNS formulation. Both provide a great deal of additional detail, including construction of vertex operators and \( S \)-matrices in the two formalisms. A concise and quite readable introduction to the problem of fermion vertex operators in the RNS formulation is provided by the lectures of Peskin (1987).

Exercises

1. Consider the R–R sectors of the IIA and IIB theories, and study the objects

\[ \bar{u} \gamma^{JK...} u. \]

Show that in the IIA case, only even-rank tensors are non-vanishing, while in the IIB theory only the odd-rank tensors are non-vanishing. Phrase this in the language of ten dimensions, rather than the eight light cone dimensions. To do this consider a particle moving along the 9 direction, and show that the Dirac equation correlates chirality in ten dimensions with chirality in eight. To do this, you may want to make the following choice of \( \gamma \) matrices:

\[ \Gamma^0 = \sigma_2 \otimes I_{16}; \quad \Gamma^i = i \sigma_1 \otimes \gamma^i; \quad \Gamma^9 = i \sigma_3 \otimes I_{16}. \quad (22.66) \]

2. Write the Green–Schwarz Lagrangian in a superspace formulation. Show that \( Q^a \) is the supersymmetry generator expected in this approach. Construct the symmetry generated by \( Q^a \), and show that this has the structure of a non-linearly realized (spontaneously broken) supersymmetry. Can you offer some interpretation?
(3) Verify that with the choice of Eq. (22.55), the zero modes of the Green–Schwarz operators $S^a$ obey the correct anticommutation relations.

(4) Verify the expression for the partition function for the Type II theories. Show that it is modular invariant. Consider a different choice, which defines the type 0 superstring,

$$|Z_0^0|^8 + |Z_0^1|^8 + |Z_1^1|^8.$$  (22.67)

If you like, verify that this is also modular invariant, but at least show that the spectrum does not include a spin-3/2 particle.

(5) Verify that the operator product of two graviton vertex operators in the RNS formalism yields the correct on-shell coupling of three gravitons. Remember the gauge condition in this analysis. The three-graviton vertex in Einstein’s theory can be found, for example, in Sannan (1986).
In the Type II theory, we have seen that the left and right movers are essentially independent. At the level of the two-dimensional Lagrangian, there is a reflection symmetry between left and right movers. However, this symmetry does not hold sector by sector; it is broken by boundary conditions and projectors.

In the heterotic theory, this independence is taken further, and the degrees of freedom of the left and right movers are taken to be independent – and different. There are two convenient world sheet realizations of this theory, known as the fermionic and bosonic formulations. In both, there are eight left-moving and eight right-moving $X^I$s, associated with ten flat coordinates in space-time. There are eight right-moving two-dimensional fermions, $\psi^I$. There is a right-moving supersymmetry, but no left-moving supersymmetry. In the fermionic formulation there are, in addition, 32 left-moving fermions which have no obvious connection with space-time, $\lambda^A$. In the bosonic description, there are an additional 16 left-moving bosons. In other words, there are 24 left-moving bosonic degrees of freedom. There are actually several heterotic string theories in ten dimensions. Rather than attempt a systematic construction, we will describe the two supersymmetric examples. These have gauge group $O(32)$ and $E_8 \times E_8$. The group $E_8$, one of the exceptional groups in Cartan’s classification, is not terribly familiar to most physicists. However, it is in this theory that we can most easily find solutions which resemble the Standard Model. We will introduce certain features of $E_8$ group theory as we need them. More detail can be found in the suggested reading. In this chapter, we will work principally in the fermionic formulation. We will develop some features of the bosonic formulation in later chapters, once we have introduced compactification of strings.
23.1 The $O(32)$ theory

The $O(32)(SO(32))$ theory is somewhat simpler to write down, so we develop it first. In this theory, the 32 $\lambda^A$ fields are taken to be on an equal footing. The GSO projector, for the right movers, is as in the superstring theory. In the RNS formalism, in the NS sector, we keep only states of odd fermion number; similarly in the Ramond sector, where fermion number includes a factor $e^{i\Gamma_{11}}$. For the left movers, the conditions are different. Again, we have a Ramond and an NS sector. In the NS sector we keep states only of even fermion number. In the R sector, the ground state is a spinor of $SO(32)$. The spinor representation can be constructed just as we constructed the spinor representation of $O(8)$. Again, there are two inequivalent irreducible representations. There is a chirality, which we can call $\Gamma_{33}$. The lowest spinor representation of definite chirality is the 32 768. Again, in the Ramond sector, we project (by convention) onto states of even “fermion number.”

As for the superstring, there is a different light cone Hamiltonian for each sector. The right-moving contributions are just as in the superstring. The left-moving part includes a contribution from the bosonic operators, and a contribution from the fermions, $\lambda^A$. As for the superstring, in the Ramond sector the $\lambda^A$s are integer moded; they are half-integer moded in the NS sector. From our formula, the left-moving normal ordering constant is $-1$.

With this, we can consider the spectrum. Take, first, the NS–NS sector, i.e. the sector with NS boundary conditions for both the left and the right movers. The states are space-time bosons. The left-moving normal ordering constant is $-1$. Without $\lambda^A$s, the lowest mass states we can form are:

$$\tilde{\alpha}_{-1}^I \psi_{-1/2}^J |0\rangle.$$  (23.1)

From our discussion of the normal ordering constants, we see that these states are massless. They have the quantum numbers of a graviton, antisymmetric tensor, and scalar field.

Using the left-moving fermion operators, we can construct additional massless states in this sector:

$$\lambda_{-1/2}^A \lambda_{-1/2}^B \psi_{-1/2}^J |0\rangle.$$  (23.2)

These are vectors in space-time. Because the $\lambda^A$s are fermions, they are antisymmetric under $A \leftrightarrow B$. So they are naturally identified as gauge bosons of the gauge group $SO(32)$. We will show shortly that they have the couplings of $O(32)$ Yang–Mills theories.

Let’s first consider the other sectors. In the NS–R sector, the right-moving states, $\psi_{-1/2}^J |\vec{p}\rangle$, are replaced by the states we labeled $|a\rangle$. Again, these must be massless, so we now have particles with the quantum numbers of the gravitino, one additional
fermion, and gauginos of $O(32)$. In the NS–R and R–R sectors, however, it turns out that there are no massless states, as can be seen by computing the normal ordering constants. It is necessary to include, as well, the R sector for the left movers. Here the normal ordering constant is $+1$, and there are no massless states.

### 23.2 The $E_8 \times E_8$ theory

The $E_8$ group is unfamiliar to many physicists, and one might wonder how one could obtain two such groups from a string theory. To begin, it is useful to note that $E_8$ has an $O(16)$ subgroup. Under this group, the adjoint of $E_8$, which is 248-dimensional, decomposes as a 120 – the adjoint of $O(16)$ – and a 128, a spinor of $O(16)$.

In ten dimensions, we have seen we can build a sensible string theory with eight left-moving bosons and 32 left-moving fermions. So the strategy is to break the fermions into two groups of 16, $\lambda^A$ and $\lambda^{\tilde{A}}$, and to treat these as independent. This gives a manifest $O(16) \times O(16)$ symmetry, similar to the symmetry of the $O(32)$ theory. There are now NS and R sectors for each set of fermions separately. The right-moving GSO projectors are as before. For the left movers, in each of the NS sectors, the left-moving projector is onto states of even fermion number. With a suitable convention for the $\Gamma_{11}$ chirality, this is also true of the R sectors. So consider, again, the spectrum. In the NS–NS–NS sector, just as before, there are a graviton, antisymmetric tensor, and scalar field. We can also construct gauge bosons in the adjoint of each of the two $O(16)$s:

$$\lambda^A \lambda^B \psi^J_{-1/2} |0\rangle \quad \lambda^{\tilde{A}} \lambda^{\tilde{B}} \psi^J_{-1/2} |0\rangle. \quad (23.3)$$

Note that because of the projectors, there are no massless states carrying quantum numbers of both $O(16)$ groups simultaneously. In the NS–NS–R sector, we find the superpartners of these fields.

Now consider the R–NS–NS sector. Here the ground state is a spinor of the first $O(16)$. So now we have a set of gauge bosons in the spinor 128-dimensional representation. Similarly, in the NS–R–NS sector, we have a spinor of the other $O(16)$. These are the correct set of states to form the adjoints of two $E_8$s. Again, establishing that the group is actually $E_8 \times E_8$ requires showing that the gauge bosons interact correctly. We will do that in the following section.

Finally, in the R–R–NS and R–R–R sectors, there are no massless states.

### 23.3 Heterotic string interactions

We would like to show that the states we have identified as gauge bosons in the heterotic string interact at low energies as required by Yang–Mills gauge invariance.
To do this, we work in the covariant formulation and construct vertex operators corresponding to the various states. Consider the $O(32)$ theory first. With our putative gauge bosons, we associate the vertex operators:

$$
\int d^2 z \, V^{AB\mu} = \int d^2 \bar{z} \lambda^A(\bar{z}) \lambda^B(\bar{z}) (\partial_\mu X^\mu(z) - i k_\nu \psi^\mu \psi^\nu(z)) e^{ik \cdot x}.
$$

(23.4)

For the right movers, as in the Type II theories, we have required invariance under the right-moving world sheet supersymmetry. For the left-moving vertex operators, we have simply required that the operators have dimension one, so that overall the vertex operator has dimension one with respect to the left- and right-moving conformal symmetry (the operator is said to be $(1, 1)$, just like those of the Type II theory). To determine their interactions, we study the operator product of two such operators. The left-moving part of the vertex operator is a current:

$$
J^{AB}(\bar{z}) = \lambda^A(\bar{z}) \lambda^B(\bar{z}).
$$

(23.5)

The operator product of two of these currents is:

$$
J^{AB}(\bar{z}) J^{CD}(\bar{w}) = \frac{\delta^{AC} \delta^{BD} + \cdots}{(\bar{z} - \bar{w})^2} + \frac{\delta^{AC} \lambda^B(\bar{z}) \lambda^D(\bar{w})}{(\bar{z} - \bar{w})^3}.
$$

(23.6)

An algebra of currents of this kind is called a “Kac–Moody algebra.” It has the general form

$$
J^a(\bar{z}) J^b(\bar{w}) = \frac{k \delta^{ab}}{(\bar{z} - \bar{w})^2} + \frac{f^{abc} J^c(\bar{w})}{(\bar{z} - \bar{w})},
$$

(23.7)

where $k$ is called the central extension of the algebra. In our case, $k = 1$. The $f^{abc}$s are the structure constants of the group. This is what we have found here.

To see the Yang–Mills structure, it is helpful to use the general Kac–Moody form, denoting the currents, and the corresponding vertex operators, by a subscript $a$. In the operator product, we have seen from our discussion of factorization that the interaction is proportional to the coefficient of $1/|z - w|^2$. In the product $V_a(z)V_b(w)$, the $1/(\bar{z} - \bar{w})$ is proportional to $f_{abc}$, just what is needed for the Yang–Mills vertex. The momentum and $g_{\mu\nu}$ pieces arise from the right-moving operator product. In

$$
(\partial X^\mu(z) + k_1 \psi^\rho(z) \psi^\mu(z)) e^{ik_1 \cdot X(z)} (\partial X^\nu(w) + k_2 \psi^\sigma(w) \psi^\nu(w)) e^{ik_2 \cdot X(w)}
$$

(23.8)

the $1/(\bar{z} - \bar{w})$ terms arise from various sources. One can contract the $\partial X$ factors in each vertex with the exponential factors. This gives

$$
V^\mu_a V^\nu_b \sim \frac{f^{abc} V^{cv}}{|z - w|^2} (k_2^\mu - k_1^\mu).
$$

(23.9)
Contracting the two $\partial X$ factors with each other gives two factors of $z - w$ in the denominator. These can be compensated by Taylor expanding $X(z)$ about $w$. Additional terms arise from contracting the fermions with each other. The details of collecting all the terms and comparing with the three gauge boson vertex are left for the exercises.

### 23.4 A non-supersymmetric heterotic string theory

One can verify the modular invariance of the heterotic string theory, with the GSO projections we have used, in precisely the same way as we did for the superstring theories. This raises the question: are there other ten-dimensional heterotic theories, obtained by combining the partition functions of the separate sectors in different ways? The answer is definitely yes. Several of these have tachyons, but one does not. Its gauge group is $O(16) \times O(16)$. It is most readily described in the Green–Schwarz formalism. This will also provide us with our first example of “modding out,” obtaining a new string theory by making various projections.

In order to obtain the smaller gauge group, we need to get rid of the gauge bosons from $E_8$ which lie in the spinor representation. On the other hand, there is no harm in having the corresponding gauginos, if supersymmetry is broken. So we take the original $E_8 \times E_8$ theory, and keep only states which are even under the symmetry $(-1)^F$ in spacetime and a corresponding symmetry in the gauge group (i.e. spinorial representations are odd, non-spinorial even). This immediately gets rid of:

1. the gravitinos, and
2. the gauge bosons which are in spinorial representations of the group.

However, we have seen that, for consistency, it is important that string theories be modular invariant. Simply throwing away states spoils modular invariance; it is necessary to add in additional states. In the present case, one has to add a sector with different, twisted boundary conditions for the fields:

$$ S_a(\sigma + \pi, \tau) = -S_a(\sigma, \tau). \quad (23.10) $$

For the gauge fermions there is a related boundary condition (this is more easily described in the bosonic formulation which we will discuss in the chapter on compactification).

### Suggested reading

The original heterotic string papers by Gross et al. (1985, 1986) are remarkably clear. Polchinski’s book (1998) provides a quite thorough overview of these theories.
For example, for those who are not enamored of the Green–Schwarz formalism, it develops the non-supersymmetric $O(32)$ in the RNS formalism in some detail.

**Exercises**

(1) Construct the states corresponding to the gauge bosons of $E_8 \times E_8$. In particular, use the creation–annihilation operator construction of $O(2N)$ spinor representations to build the 128s of $O(16)$.

(2) Verify that the algebra of $O(32)$ currents is of the Kac–Moody form. To work out the structure constants, remember that the generators of $O$ groups are just the antisymmetric matrices:

$$\omega^{AB}_{\phantom{AB}CD} = \delta^{AC} \delta^{BD} - \delta^{AD} \delta^{BC}.$$  

(23.11)

(3) Verify that, on-shell, the three-gluon vertex has the correct form. In addition to carefully evaluating the terms in the operator product expansion, it may be necessary to use momentum conservation and the transversality of the polarization vectors.
In ten dimensions, supersymmetry greatly restricts the allowed particle content and effective actions for theories with massless fields. Without gauge interactions, there are only two consistent possibilities. These correspond to the low-energy limits of the IIA and IIB theories. These have $N = 2$ supersymmetry (they have 32 conserved supercharges). Because the symmetry is so restrictive, we can understand a great deal about the low-energy limits of these theories without making any detailed computations. We can even make exact statements about the non-perturbative behavior of these theories. This is familiar from our studies of field theories in four dimensions with more than four supercharges. In ten dimensions, supersymmetric gauge theories have $N = 1$ supersymmetry (16 supercharges). Classically, specification of the gauge group completely specifies the terms in the effective action with up to two derivatives. Quantum mechanically, only the gauge groups $O(32)$ and $E_8 \times E_8$ are possible.

24.0.1 Eleven-dimensional supergravity

Rather than start with these ten-dimensional theories, it is instructive to start in eleven dimensions. Eleven is the highest dimension where one can write a supersymmetric action (in higher dimensions, spins higher than two are required). This fact by itself has focused much attention on this theory. But it is also known that eleven dimensions has a connection to string theory. As we will see later, if one takes the strong coupling limit of the Type IIA string theory, one obtains a theory whose low-energy limit is eleven-dimensional supergravity.

The particle content of the eleven-dimensional theory is simple: there is a graviton, $g_{MN}$ (44 degrees of freedom) and a three-index antisymmetric tensor field, $C_{MNO}$ (84 degrees of freedom). There is also a gravitino, $\psi_M$. This has $(16 \times 8)$ degrees of freedom. We have, as usual, counted degrees of freedom by considering a theory in nine dimensions, remembering that $g_{MN}$ is symmetric and traceless,
and that the basic spinor representation in nine dimensions is sixteen dimensional (it combines the two eight-dimensional spinors of \(O(8)\)).

The Lagrangian for the eleven-dimensional theory, in addition to the Ricci scalar, involves a field strength for the three-index field, \(C_{MNO}\). The corresponding field strength, \(F_{MNPQ}\), is completely antisymmetric in its indices, similar to the field strength of electrodynamics:

\[
F_{MNPQ} = \frac{3!}{4!} \left( \partial_M C_{NOP} - \partial_N C_{MOP} + \cdots \right)
= \frac{3!}{4!} \sum_p (-1)^p \partial_M C_{NOP},
\]

(24.1)

where the sum is over all permutations, and the factor \((-1)^p\) is \pm 1 depending on whether the permutation is even or odd. It is convenient to describe such antisymmetric tensor fields in the language of differential forms. For the reader unfamiliar with these, an introduction is provided later, in Section 26.1. For now, we note that antisymmetric tensors with \(p\) indices are \(p\) forms. The operator of taking the curl, as in Eq. (24.1), takes a \(p\) form to a \(p + 1\) form. It is denoted by the symbol \(d\), and is called the exterior derivative. In terms of forms, Eq. (24.1) can be written quite compactly as

\[
F = dC.
\]

(24.2)

The theory has a gauge invariance:

\[
C \rightarrow C + d\Lambda \quad C_{MNO} \rightarrow \frac{2}{3!} \sum_p (-1)^p \partial_M \Lambda_{NO}
\]

(24.3)

where \(\Lambda\) is a two-form.

We will not need the complete form of the action. The bosonic terms are:

\[
\mathcal{L}_{\text{bos}} = -\frac{1}{2\kappa^2} \sqrt{g} R - \frac{1}{48} \sqrt{g} F_{MNPQ}^2 - \frac{\sqrt{2}}{3456} \kappa^{M_1 \ldots M_{11}} F_{M_1 \ldots M_4} F_{M_5 \ldots M_8} C_{M_9 \ldots M_{11}}.
\]

(24.4)

The last term is a Chern–Simons term. It respects the gauge invariance of Eq. (24.3) if one integrates by parts. Such terms can arise in field theories with odd dimensions; in 2+1-dimensional electrodynamics, for example, they play an interesting role. The fermionic terms include covariant derivative terms for the gravitino, as well as couplings to \(F\) and various four-Fermi terms. The supersymmetry transformation laws have the structure:

\[
\delta e^A_M = \frac{\kappa}{2} \bar{\eta} \Gamma^A \psi_M
\]

(24.5)

\[
\delta A_{MNP} = -\frac{\sqrt{2}}{8} \bar{\eta} \Gamma_{[MNP]} \psi_P
\]

(24.6)

\[
\delta \psi_M = \frac{1}{\kappa} D_M \eta + (F \eta \text{ pieces}).
\]

(24.7)
Here $e^A_M$ is the “vielbein” field, and the covariant derivative is constructed from the spin connection (discussed in Section 17.6).

### 24.0.2 The IIA and IIB supergravity theories

The eleven-dimensional fields are functions of the coordinates $x_0, \ldots, x_{10}$. We obtain the IIA supergravity theory (the low-energy limit of the Type IIA string) theory if we truncate the eleven-dimensional supergravity theory to ten dimensions, i.e. if we simply eliminate the dependence on $x_{10}$. We need to relabel fields, as well, since it is not appropriate to have a 10 index. So we take the components of $g$ with ten-dimensional indices to be the ten-dimensional metric. Then $g_{10\,10}$ is a ten-dimensional scalar, which we call $\phi$, and $g_{10\,\mu}$ is a ten-dimensional vector, which corresponds to the Ramond–Ramond vector of the IIA string theory. Note that $C_{11\,\mu
u} = B_{\mu
u}$ is a two-index antisymmetric tensor field in ten dimensions (corresponding to the two-index tensor we found in the NS–NS sector). The gravitino decomposes into two ten-dimensional gravitinos, and two spin-1/2 particles. With $H = dB$, the bosonic terms in the ten-dimensional action for the NS–NS fields are:

$$
L_{\text{bos}} = -\frac{1}{2\kappa^2} R - \frac{3}{4} \phi^{-3/2} H_{\mu\nu\rho}^2 - \frac{9}{16\kappa^2} (\partial_\mu \phi / \phi)^2. 
$$

The IIB theory is not obtained in this way. But from string theory, we can see that the NS–NS in the action must be the same as in the Type IIA theory. This is because in the NS–NS sector, the vertex operators of the IIA and IIB theories are the same, so the scattering amplitudes – and hence the effective action – are the same as well.

### 24.0.3 Ten-dimensional Yang–Mills theory

From our studies of the heterotic string, we know the field content of this theory. There is a metric, an antisymmetric tensor field (which we again call $B_{\mu\nu}$), a scalar $\phi$, and the gauge fields, $A^a_\mu$. The Lagrangian for $g$, $B$ and $\phi$ is the same as in the Type II theories. The gauge terms are:

$$
L_{\text{YM}} = -\frac{\phi^{-3/4}}{4g^2} F_{\mu\nu}^2 - \frac{1}{2} \bar{\chi}^a (D_M \chi)^a. 
$$

It turns out that there is another crucial modification in the Yang–Mills case. The field strength $H_{MNO}$ is not simply the curl of $B_{MN}$ but contains an additional piece, which closely resembles the Chern–Simons term we encountered in our study of instantons in four-dimensional Yang–Mills theory:

$$
H = dB - \frac{\kappa}{\sqrt{2}} \omega_3 
$$

(24.10)
(the notation will be thoroughly explained in Chapter 26), with
\[ \omega_3 = A^a F^a - \frac{1}{3} g f_{abc} A^a A^b A^c = A^a d A^a + \frac{2}{3} g f_{abc} A^a A^b A^c. \] (24.11)

There is also a gravitational piece, with a similar form.
This extra term plays an important role in understanding anomaly cancellation. In four dimensions, we will see that it leads to the appearance of axions in the low-energy theory.

### 24.1 Coupling constants in string theory

The Standard Model is defined, in part, by specifying a set of coupling constants. The fact that there are so many parameters is one of the reasons we have given that the model is not satisfactory as some sort of ultimate description of nature. In our discussion of string interactions, we have introduced a coupling constant, \( g_s \). There is one such constant for each of the string theories we have introduced: bosonic, Type I, Type IIA and Type IIB, and heterotic. But the idea that string theory possesses a free parameter is, it turns out, an illusion. By changing the expectation value of the dilaton field, we can change the value of the coupling. This is similar to phenomena we observed in four-dimensional supersymmetric gauge theories. In situations with a great deal of supersymmetry, there will be no potential, perturbatively or non-perturbatively, for this field, and the choice of coupling will correspond to a choice of vacuum. But in vacua in which supersymmetry is broken, we would expect that dynamical effects would fix the value of this and any other moduli. The coupling constants of the low-energy theory would then be determined fully in ways which, in principle, one could understand and eventually hope to calculate. In the next few sections, we explain this connection between coupling constants and fields.

#### 24.1.1 Couplings in closed string theories

When we constructed vertex operators, we saw that we could include a coupling constant, \( g_s \), in the definition of the vertex operator. In the heterotic string, the same coupling enters in all vertices. This is a consequence of unitarity. At tree level, for example, we saw that scattering amplitudes factorize near poles of the \( S \)-matrix. If one introduced independent couplings for each vertex operator, the amplitudes would not factorize correctly. As a result, all amplitudes can be expressed in terms of a single parameter. In the heterotic string theory, this means that there is a calculable relation between the gravitational constant and the Yang–Mills coupling. To work out this coupling, one needs to calculate the three-point interaction for three
Coupling constants in string theory

24.1.2 The coupling is not a parameter in string theory

So far, in all of the string theories, it appears that there is an adjustable, dimensionless parameter. As we said earlier, this is not really the case. The reason for this traces to the dilaton. Classically, in all of the string theories we have studied, the dilaton has no potential, so its expectation value is not fixed. In the next two short sections, we will demonstrate that changing the expectation value of the dilaton changes the effective coupling. With enough supersymmetry, there is no potential for the dilaton, so the question of the value of the coupling is equivalent to a choice among degenerate vacuum states. Without supersymmetry (or with \( N \leq 1 \) supersymmetry in four dimensions), one does expect quantum mechanical effects to generate a potential for the dilaton, and the value of the coupling is a dynamical question.

24.1.3 Effective Lagrangian argument

Perhaps the simplest way to understand the role of the dilaton is to examine the ten-dimensional effective action. Start with the case of the heterotic string in ten dimensions. We can redefine \( \phi = g^{-2}\kappa^{3/2}\phi' \), eliminating \( g \) everywhere in the action. Note that, since \( \kappa \propto g \), this means that \( \phi' \sim g^{1/2} \). Then we can do a Weyl rescaling which puts a common power of \( \phi \) in front of the action (dropping the prime on \( \phi \)):

\[
g_{\mu\nu} = \phi^{-1}g_{\mu\nu}
\]

puts a common power of \( \phi \) out front of the action: \( \phi^{-4} \). This is consistent with \( g \) being the string loop parameter, since we have effectively \( g^{-2} \) at the front.

With this rescaling, it is the string scale which is fundamental. Remember that \( M_p^2 = M_s^2/(g^2)^{1/4} \). By rescaling the metric, we have rescaled lengths, which were originally expressed in units of \( M_p \), in terms of \( M_s \). So we have a consistent picture.
The cutoff for the effective Lagrangian is $M_s$. All dimensional parameters in the Lagrangian are of order $M_s$, and loops are accompanied by $g^2 \sim \phi^4$.

### 24.1.4 World sheet coupling of the dilaton

Just as we can couple the graviton to the world sheet, we can couple the dilaton. The dilaton turns out to couple to the two-dimensional curvature:

$$\mathcal{L}_\Phi = \frac{1}{4\pi} \int d^2\sigma \sqrt{h} \Phi(X) R^{(2)}.$$  \hfill (24.15)

In two dimensions, however, gravity is “trivial.” If we use our usual counting rules, the graviton has $-1$ degree of freedom. So the $R^{(2)}$ term should not generate any sensible graviton dynamics. If we go to conformal gauge,

$$h_{\alpha\beta} = e^{\phi} \eta_{\alpha\beta}$$  \hfill (24.16)

the curvature is a total divergence:

$$R^{(2)} = \partial^2 \phi.$$  \hfill (24.17)

So at most this term in the action is topological. To get some feeling for this, let’s evaluate the integral in the case of a sphere. We have seen that one representation for the sphere is provided by the space $\mathbb{C}P^1$. This space has one complex coordinate. It is Kahler, which means that the only non-vanishing component of $g$ is $g_{z\bar{z}}$:

$$g_{z\bar{z}} = (\partial_z \partial_{\bar{z}} K(z, \bar{z}))$$  \hfill (24.18)

where, in this case:

$$K = \ln(1 + \bar{z} z).$$  \hfill (24.19)

So

$$g = \left(\frac{1}{1 + \bar{z} z}\right)^2.$$  \hfill (24.20)

From this, we can read off $\phi$:

$$\phi = 2 \ln(1 + \bar{z} z) = -2 \ln \left(1 + \sigma_x^2 + \sigma_y^2\right)$$  \hfill (24.21)

so the integral over the curvature is:

$$\frac{1}{4\pi} \int d^2\sigma \partial^2 \left(-2 \ln \left(1 + \sigma_x^2 + \sigma_y^2\right)\right) = 2.$$  \hfill (24.22)
Note that this is invariant under a constant Weyl rescaling; it is topological. It is known as the Euler character of the surface, and satisfies:

\[ \chi = \frac{1}{4\pi} \int d^2 \sigma \sqrt{h} R^{(2)} \]  \hspace{1cm} (24.23)

and

\[ \chi = 2(1 - g). \]  \hspace{1cm} (24.24)

In this expression, \( \chi \) is known as the Euler character of the manifold, and \( g \) is the genus. For the sphere, \( g = 0 \); for the torus, \( g = 1 \), and so on for higher-genus string amplitudes. So string amplitudes, for constant \( \Phi \), come with a factor:

\[ e^{-2\Phi(1-g)}. \]  \hspace{1cm} (24.25)

So we can identify \( e^\Phi \) with the string coupling constant.

**Suggested reading**

The ten-dimensional effective actions are described in some detail by Green *et al.* (1987). The couplings of the dilaton in string theory are discussed in detail by Polchinski (1998).

**Exercise**

(1) By studying the OPEs of the appropriate vertex operators, verify Eq. (24.12). To avoid making this calculation too involved, you may want to isolate particular terms in the gravitational and Yang–Mills couplings. The required vertices in general relativity can be found in Sannan (1986).
We don’t live in a ten-dimensional world, and certainly not in a twenty-six-dimensional world without fermions. But if we don’t insist on Lorentz invariance in all directions, there are other possible ways to construct consistent string theories. In this chapter we will uncover many consistent string theories in four dimensions (and in others). If anything, our problem will shortly be an embarrassment of riches: we will see that there are vast numbers of possible string constructions. The connection of these various constructions to one another is not always clear. Many of these can be obtained from one another by varying expectation values of light fields (moduli). One might imagine that others could be obtained by exciting massive fields as well. In general, though, this is not known, and, in any case, the meaning of such connections in a theory of gravity is obscure. But before exploring these deep and difficult questions, we need to acquire some experience with constructing strings in different dimensions.

25.1 Compactification in field theory: the Kaluza–Klein program

The idea that space-time might be more than four-dimensional was first put forward by Kaluza and Klein shortly after Einstein published his general theory of relativity. They argued that, in this case, five-dimensional general coordinate invariance would give rise to both four-dimensional general coordinate invariance and a $U(1)$ gauge invariance, unifying electromagnetism and gravity. In modern language, they considered the possibility that space-time is five-dimensional, with the structure $M^4 \times S^1$. This is, on first exposure, a bizarre concept, but its implications are readily understood by considering a toy model. Take a single scalar field, $\Phi$, in five dimensions. Denote the coordinates of $M^4$ by $x^\mu$, as usual, and that of the fifth dimension by $y$,

$$0 \leq y < 2\pi R.$$  \hfill (25.1)
Because $y$ is a periodic variable, we can expand the field $\Phi$ in Fourier modes:

$$\Phi(x, y) = \sum_n \frac{1}{\sqrt{2\pi R}} \phi_n(x) e^{ip_n y} \quad p_n = \frac{n}{R}. \tag{25.2}$$

Taking a simple free field Lagrangian for $\Phi$ in five dimensions, the Lagrangian, written in terms of the Fourier modes, takes the form:

$$\int d^4xdy L = -\int d^4xdy \frac{1}{2} \left[ (\partial\phi)^2 + M^2 \phi^2 \right]$$

$$= -\int d^4x \sum_n \frac{1}{2} \left( \partial_\mu \phi + (M^2 + p_n^2) \phi \right)^2. \tag{25.3}$$

So, from a four-dimensional perspective, this theory describes an infinite number of fields, with ever increasing mass. In the gravitational case, symmetry considerations will force $M = 0$. If we set $M = 0$ in our scalar model, we obtain one massless state in four dimensions ($n = 0$), and an infinite tower – the Kaluza–Klein tower – of massive states. If $R$ is very small, say $R \approx M^{-1}_p$, the massive states are all extremely heavy. For the physics of the every-day world, we can integrate out these massive fields, and obtain an effective Lagrangian for the massless field. The effects of the infinite set of massive fields – the signature of extra dimensions – will show up in tiny, higher-dimension operators. So, in the end, finding evidence for these extra dimensions is likely to be extremely difficult.

Having understood this simple model, we can understand Kaluza and Klein’s theory of gravitation and electromagnetism. The five-dimensional theory has the Lagrangian:

$$\mathcal{L} = \frac{1}{2\kappa^2} \sqrt{g} R. \tag{25.4}$$

Now there is an infinite tower of massive states, corresponding to modes of the five-dimensional metric: $g_{\mu\nu}$, $g_{\mu 4}$ and $g_{44}$. Our principal interest is in the massless states, which arise from modes which are independent of $y$ (we will need to refine this identification shortly). We expect to find a four-dimensional metric tensor, $g_{\mu\nu}$, a field which transforms as a vector of the four-dimensional Lorentz group, $g_{4\mu}$, and a scalar: $g_{44}$. There are various ways we can rewrite the five-dimensional fields in terms of four-dimensional fields. The physics is independent of this choice, but clearly some choices will be better than others. The most sensitive choice is that of the gauge field; we would like to choose this field so that its gauge transformation properties are simple. The general coordinate invariance associated with transformations of the fifth dimension, $x_4 = x_4 + \epsilon_4(x)$, is:

$$g_{\mu 4} = g_{\mu 4} + \partial_\mu \epsilon_4(x). \tag{25.5}$$
This looks just like the transformation of a gauge field. So we adopt the conventions:

$$g_{\mu 4} = A_\mu; \quad g_{44}(x) = e^{2\sigma(x)}; \quad g_{\mu \nu} = g_{\mu \nu}.$$  \hfill (25.6)

Note we are defining, here, a reference metric and measuring distances relative to that; we can take the basic distance to be the Planck length. Substituting this Ansatz back in the five-dimensional action, one can proceed very straightforwardly, working out the Christoffel symbols and from these the various components of the curvature. Gauge invariance significantly constrains the possible terms. One obtains:

$$L = \frac{2\pi R}{2\kappa^2} \sqrt{g} e^\sigma (R) + \frac{1}{4} e^{-\sigma} F_{\mu \nu}^2.$$  \hfill (25.7)

So the theory, at low energies, consists of a $U(1)$ gauge field, the graviton, and a scalar. The Lagrangian is not quite in the canonical form; usually one writes the action for general relativity in a form where the coefficient of the Ricci scalar (the “Einstein term”) is field-independent. One can achieve this by performing an overall rescaling of the metric, known as a Weyl rescaling,

$$g_{\mu \nu} \rightarrow e^{-\sigma} g_{\mu \nu}.$$  \hfill (25.8)

This introduces a kinetic term for the scalar:

$$L = \frac{1}{2\kappa^2} (R + 3/2 (\partial \phi)^2).$$  \hfill (25.9)

The scalar field here is particularly significant. As it corresponds to $g_{55}$, giving it an expectation value amounts to changing the radius of the internal space. In the Lagrangian, there is no potential for $\sigma$, so at this level, nothing determines this expectation value. As in our four-dimensional examples, $\sigma$ is said to be a modulus.

We now show that quantum mechanical effects generate a potential for $\sigma$, already at one loop. This potential falls to zero rapidly as the radius becomes large. If there is a minimum of the potential, it occurs at radii of order one, where the computation is certainly not reliable.

The calculation is equivalent to a Casimir energy computation in quantum field theory; one can think of the system as sitting in a periodic box of size $2\pi R$, and asking how the energy depends on the size of the box. We can guess the form of the answer before doing any calculation. Since this is a one-loop computation, the result is independent of the coupling. On dimensional grounds, the energy density is proportional to $1/R^4$.

To simplify matters, we will treat the gravitational field as a scalar field. At one loop:

$$\Gamma = \text{Tr} \ln \left( -\partial^2 + \frac{n^2}{R^2} \right),$$  \hfill (25.10)
where we can do the calculation in Euclidean space. We can obtain a more manageable expression by differentiating with respect to $R$. The trace can be interpreted now as a sum over the possible momentum states in four Euclidean dimensions, in a box of volume $VT$. Replacing the sum by an integral gives an explicit factor of $VT$; the coefficient is the energy per unit volume:

$$\frac{\partial V}{\partial R} = \int \frac{d^4 p}{(2\pi)^4 R^3} \sum_n \frac{n^2}{p^2 + (n^2/R^2)}.$$  \hspace{1cm} (25.11)

This can be evaluated using the same trick one uses to compute the partition function in finite-temperature field theory (this is described in Appendix C). One first converts the sum into a contour integral, by introducing a function with simple poles located at the integers:

$$\frac{\partial V}{\partial R} = \int \frac{d^4 p}{(2\pi)^3} \oint dz \frac{1}{2\pi i} \frac{1}{z^2 + p^2} \frac{1}{1 - e^{2\pi i R z} z^2/R}.$$  \hspace{1cm} (25.12)

The contour consists of one line running slightly above the real axis, and one line running below. Now deform the contour, so that the upper line encircles the pole at $z = ip$, and the lower line encircles the pole at $z = -ip$. The resulting expression is divergent, but we can separate off a piece independent of $R$ and a convergent, $R$-dependent piece:

$$\frac{\partial V}{\partial R} = \frac{1}{R} \int \frac{d^4 p}{(2\pi)^4} \frac{p^2}{2p} \left[ 1 + \frac{1}{e^{2\pi p R} - 1} \right] = \frac{24\zeta[5]}{(2\pi)^4 R^5} + R\text{-independent.}$$  \hspace{1cm} (25.13)

### 25.1.1 Generalizations and limitations of the Kaluza–Klein program

So far we have considered compactification of a five-dimensional theory on a circle, but one can clearly consider compactifications of more dimensions on more complicated manifolds. It is possible to obtain, in this way, non-Abelian groups. So one might hope to understand the interactions of the Standard Model. The principal obstacle to such a program turns out to be obtaining chiral fermions in suitable representations. The existence of chiral fermions in a particular compactification is a topological question. As one varies the size and shape of the manifold, it is possible that some fields will become massless; equivalently, massless fields can become massive. But fields which gain mass must come in vector-like pairs. Chiral fermions will not simply appear or disappear as one continuously changes the parameters of the compactification. Spinors in higher dimensions decompose as left–right symmetric pairs with respect to four dimensions, but for suitable compactification manifolds, it is possible to obtain chiral fermions. However, it turns out to be impossible
to obtain chiral fermions in the required representations of the Standard Model group. We will see, though, that string theory can generate both gauge groups and chiral fermions upon compactification.

25.2 Closed strings on tori

So far we have considered compactifications of field theories in higher dimensions. But general higher-dimensional field theories are non-renormalizable, and must be viewed as low-energy limits of some other structure. The only sensible structure we know in higher dimensions is string theory. At the same time, if string theory is to have anything to do with the world around us, it must be compactified to four dimensions.

It is not complicated to repeat this analysis for the case of closed strings on circles, or more generally on tori. Consider first compactifying one dimension, $X^9$, on a circle of radius $2\pi R$. We require that states be invariant under translations by $2\pi R$. This means that the momenta, as in the field theory case, are quantized,

$$p^9 = \frac{n}{R}.$$  \tag{25.14}

But now there is a new feature. Because of the identification of points, the string fields themselves ($X^9$) need not be strictly periodic. Instead, we now have the mode expansion:

$$X^9 = x^9 + p^9\tau + 2mR\sigma + \frac{i}{2} \sum_{n \neq 0} \frac{1}{n} \left( \alpha_n^9 e^{-in(\tau-\sigma)} + \tilde{\alpha}_n^9 e^{-in(\tau+\sigma)} \right), \tag{25.15}$$

where $m$ is an integer. The states with non-zero $m$ are called “winding” states. They correspond to the possibility of a string winding around, or wrapping, the extra dimension. Now the mass operator, in addition to including a contribution $(p^9)^2 = n^2/R^2$, includes, as well, a contribution from the windings, $m^2R^2$ (if there is no momentum). If $R$ is large compared with the string scale, these states are very heavy. At small $R$, however, these states become light, while the momentum (Kaluza–Klein) states become heavy. This reciprocity often corresponds, as we will see, to a symmetry between compactification at large and at small radius.

Let’s focus on the various superstring theories. It is convenient to break up $X^9$ in terms of left- and right-moving fields:

$$X^9_L = \frac{x^9}{2} + \left( \frac{n}{2R} + mR \right) (\tau - \sigma) + \frac{i}{2} \sum_{n \neq 0} \frac{1}{n} \alpha_n^9 e^{-in(\tau-\sigma)}$$ \tag{25.16}

$$X^9_R = \frac{x^9}{2} + \left( \frac{n}{2R} - mR \right) (\tau + \sigma) + \frac{i}{2} \sum_{n \neq 0} \frac{1}{n} \tilde{\alpha}_n^9 e^{-in(\tau+\sigma)}.$$ \tag{25.17}
It is then natural to define left- and right-moving momenta:

\[ p_L = \frac{n}{2R} + mR \quad p_R = \frac{n}{2R} - mR. \]  

(25.18)

The world-sheet fermions are untouched by this compactification. The mass operators are essentially as before, with \( p \) replaced by \( p_L \) for the left movers and \( p_R \) for the right movers:

\[ L_0 = \frac{1}{2} p_L^2 + N \quad \tilde{L}_0 = \frac{1}{2} p_R^2 + \tilde{N}. \]  

(25.19)

Suppose we compactify on a simple product of circles. The left- and right-moving momenta form a lattice:

\[ p_{L}^I = \frac{n_I}{R} + 2m^I R^I \quad p_{R}^I = \frac{n_I}{R} - 2m^I R^I. \]  

(25.20)

Let’s determine the spectrum, focusing on the light states. Consider, first, the heterotic string, and to simplify the formulas, we take the \( O(32) \) case. The \( O(32) \) symmetry is unbroken. The original ten-dimensional gauge bosons,

\[ |A_M^{AB}\rangle = \lambda_{-1/2}^A \lambda_{-1/2}^B \psi_M |\tfrac{1}{2}\rangle |p\rangle, \]  

(25.21)

now decompose into a set of four-dimensional gauge bosons, corresponding (in light cone gauge) to \( M = 2, 3 \), and six scalars, \( M = I \). The graviton, scalar, and antisymmetric tensor field now decompose as a set of scalars, \( g_{IJ}, B_{IJ} \), vectors \( g_{\mu}, B_{\mu I} \), a four-dimensional graviton, \( g_{\mu \nu} \), antisymmetric tensor, \( b_{\mu \nu} \), and scalar, \( \phi \).

To understand space-time fermions, work in light cone gauge, and return to our description of \( O(8) \) spinors. Group the \( \gamma \)-matrices into a set associated with the internal six dimensions, and one associated with the (transverse) Minkowski directions. In other words, instead of the four creation and annihilation operators, \( a^i, a^\dagger_i \), we group these into one set of three (labelled \( a^i \), where now \( i = 1, 2, 3 \), and \( b \), and their conjugates). So the \( 8_s \), which previously consisted of the states

\[ |0\rangle \quad a^i a^j |0\rangle \quad a^i a^2 a^3 a^4 |0\rangle, \]  

(25.22)

now decomposes as:

\[ |0\rangle \quad a^i a^j |0\rangle \quad b^i a^j |0\rangle \quad b^i a^1 a^2 a^3 |0\rangle. \]  

(25.23)

There are four states with no \( bs \), and four with one \( b \). These groups have opposite four-dimensional helicity. They can also be classified according to their transformation properties under \( O(6) \). \( O(6) \) is isomorphic to the group \( SU(4) \). We have just seen that \( 8_s = 4 + 4 \). We can also see that under the \( SU(3) \) subgroup of \( SU(4) \), the spinor decomposes as

\[ 8 = 3 + 3 + 1 + 1. \]  

(25.24)
Consider how the gravitino in ten dimensions decomposes under $O(3, 1) \times SU(4)$. We see that the gravitino consists of a set of spin-$3/2$ particles in the 4 of $SU(4)$, and their antiparticles. So, from the perspective of four dimensions, this is a theory with $N = 4$ supersymmetry. This is not really surprising since the ten-dimensional theory was a theory with 16 supercharges, and none of these are touched by this reduction to four dimensions.

Because of the high degree of SUSY, one cannot write a potential for the scalar fields, $g_{IJ}$, $b_{IJ}$, etc.; they are exact flat directions. If we redo our Casimir energy calculation, we will find that, because there is a fermionic state degenerate with every bosonic state, there is a cancellation.

What do these moduli correspond to? Those which arise from the diagonal components of the metric correspond to the fact that the radii are not fixed. There is a string solution for any value of the $R^I$. The off-diagonal components are related to the fact that the general torus in six dimensions is not simply a product of circles; there can be non-trivial angles.

The massless scalars arising from the gauge bosons, $A^I$, are also moduli. For constant values of these fields, there is no associated field strength, so they carry zero energy. But there are non-trivial Wilson lines:

$$U_I = e^{i \int_0^{2\pi R} dx^I A_I}.$$ (25.25)

Because of the periodicity, these are gauge-invariant, and correspond to distinct physical states. These moduli are often themselves called Wilson lines.

The periodicities of a general $N$-dimensional torus can be characterized in terms of $N$ basis vectors, $e^I_a$, $a = 1, \ldots, N$. The theory is defined by the identifications:

$$X^I = X^I + 2\pi n^a e^I_a.$$ (25.26)

The set of integers define a lattice. To determine the allowed momenta, we define the dual lattice, with unit vectors: $\tilde{e}^I_a$, satisfying:

$$\tilde{e}^I_a e^J_b = \delta^a_b.$$ (25.27)

In terms of these, we can write the momenta for the general torus:

$$p^I = n^a \tilde{e}^I_a,$$ (25.28)

while the windings are:

$$w^I = m^a e^I_a.$$ (25.29)

We can break these into left-moving and right-moving parts:

$$p^I_L = (p^I / 2 + w^I) \quad p^I_R = (p^I / 2 - w^I).$$ (25.30)
The lattice of left- and right-moving momenta, \((p_L, p_R)\), has some interesting features. Thought of as a Lorentzian lattice it is even and self-dual. The “even” refers to the fact that the inner product of a vector with itself:

\[
p_L^2 - p_R^2 = 2nm, \tag{25.31}
\]

is even. The self-duality means that the basis vectors of the lattice and the dual are the same (Eq. (25.27)).

In bosonic or Type II theories, these are the most general four-dimensional compactifications with \(N = 8\) supersymmetry. The different possible choices of torus define a moduli space of such theories. These moduli correspond to varying the metric and antisymmetric tensor fields. In the heterotic case, the four dimensional theory has \(N = 4\) supersymmetry. Additional moduli arise from Wilson lines. As for the simple compactification on a circle, these are essentially constant gauge fields. A constant gauge field is almost a pure gauge transformation (take \(I\) fixed, for simplicity):

\[
A^I = i e^{ix_I A^I} \partial^I e^{-ix_I A^I} = i g \partial^I g^I \tag{25.32}
\]

but the gauge transformation is only periodic if \(A^I = 1/R_I\). In this case, the Wilson line is unity. But we can do a redefinition of all of the charged fields, which eliminates the \(A^I\)s:

\[
\phi = g \phi'. \tag{25.33}
\]

With this choice, charged fields are no longer periodic, but obey boundary conditions:

\[
\phi'(X^I) = e^{2 \pi R_I A^I} \phi. \tag{25.34}
\]

This means that the momenta are shifted:

\[
p^I = \frac{n}{R_I} + A^I. \tag{25.35}
\]

Shortly, we will see how all of the different momentum lattices can be understood in terms of constant background fields.

### 25.3 Enhanced symmetries

For large radius, the spectrum of the toroidally compactified string theory is very similar to that expected from Kaluza–Klein field theories. The principal new feature, the winding states, is not important. At smaller radius, however, these states introduce startling new phenomena. We focus, first, on compactification of just one
Examining the momenta
\[ p_L = \frac{m}{2R} + nR \quad p_R = \frac{m}{2R} - nR \]  
(25.36)
we see that these are symmetric under \( R \rightarrow 1/(2R) \). This symmetry is often called 
"T-duality." It means that there is not a sense in which one can take the compactification radius to be arbitrarily small; it is our first indication that there is some sort of fundamental length scale in the theory. T-duality is not a feature of the compactification of field theory; the string windings are critical.

What is the physical significance of this symmetry? The answer depends on which string theory we study. Consider the heterotic string. We first ask whether duality is truly a symmetry, or just a feature of the spectrum. To settle this, we can check that it has a well-defined action on all vertex operators. Alternatively, we note that there is a self-dual point: \( R_{sd} = 1/\sqrt{2} \). Examining Eq. (25.19) we see that, at this radius, various states can become massless. These include both scalars (from the point of view of the non-compact dimensions) and gauge bosons:
\[ \psi^{I,\mu}_{-1/2}|n = \pm 1, m = \mp 1 \rangle. \]  
(25.37)
Together with the \( U(1) \) gauge boson, the spin-one particles form the adjoint of an \( SU(2) \). We can check this by studying the operator product expansions of the associated vertex operators (see the exercises at the end of this chapter).

Now we can understand the \( R \rightarrow 1/R \) symmetry. At the fixed point, the symmetry is an unbroken symmetry. It transforms:
\[ p_L \rightarrow -p_L \quad p_R \rightarrow p_R. \]  
(25.38)
In world sheet terms, this corresponds to a change of sign of \( \partial X_L \):
\[ \partial X_L \rightarrow -\partial X_L \quad \partial X_R \rightarrow \partial X_R. \]  
(25.39)
From (25.37), \( X_L \) is the third component of isospin, \( T_3 \) so \( T_3 \rightarrow -T_3 \) under T-duality.

This transformation is a 90° rotation about the 1 or 2 axis in the \( SU(2) \) space, i.e. it is a gauge transformation! This means that the large and small radii not merely exhibit the same physics, they are the same. It also means that, provided the theory makes sense, the symmetry is an exact symmetry of the theory, in perturbation theory and beyond. As for any gauge symmetry, any violation of the symmetry would signal an inconsistency.

Returning to the self-dual point, the momentum lattice at this point can be thought of as a group lattice, with the \( p_L \)'s labeling the \( SU(2) \) charges. Much larger symmetry groups can be obtained by making special choices of the torus, Wilson lines and antisymmetric tensor fields.
In other string theories the symmetry has a different significance. Consider the Type II theories; take the case of IIA for definiteness. Then since $\psi_R^9 \rightarrow -\psi_R^9$, the GSO projection in the right-moving Ramond sectors is flipped. So this transformation takes the Type IIA theory to the Type IIB theory. In other words, the IIA theory at large $R$ is equivalent to the IIB theory at small $R$.

25.4 Strings in background fields

The possibilities for string compactification are much richer than tori, and we will explore them in this and the next chapter. We can approach the problem in two ways, each of which is very useful. First, we can examine the low-energy effective field theory which describes the massless modes of the string in ten dimensions, and look for solutions corresponding to large internal spaces. The effective action can be organized into terms with more and more derivatives. The spaces must be large in order that this use of the low-energy effective action makes sense. Alternatively, we can look for more direct ways to construct classical solutions in string theory. Both approaches have turned out to have great value.

We will first formulate the string problem in a more general way. We want to ask: how do we describe a string propagating in a background which is not flat? The background might be described by a metric, $G_{MN}$, but it might also include an antisymmetric tensor, $B_{MN}$, a dilaton, $\phi$, and, in the case of the heterotic string, gauge fields. Let's first focus on the metric. Start with the bosonic string. It is natural to generalize the string action:

$$\frac{1}{2\pi} \int d^2 \sigma \partial_\alpha X^M \partial^\alpha X^N \eta_{MN} \tag{25.40}$$

to

$$\frac{1}{2\pi} \int d^2 \sigma \partial_\alpha X^M \partial^\alpha X^N G(X)_{MN} \tag{25.41}$$

From a world sheet point of view, we have replaced a simple free field theory with a non-trivial, interacting field theory. We can think of the $X^M$s as fields which propagate on a manifold with metric $G_{MN}$. Often this space is called the “target space” of the theory; the $X$s then provide a mapping from two-dimensional space-time to this target space.

This looks plausible, but we can give some evidence that it is the correct prescription. Suppose, in particular, we consider a metric which is nearly that of flat space:

$$G_{MN} = \eta_{MN} + h_{MN} \tag{25.42}$$
Substitute this form in the action, and examine the path integral for the field theory:

\[ Z[h] = \int [dX^M] e^{iS_0 + \frac{i}{2\pi} \int d^2 \sigma \delta_a X^M \partial^\alpha X^N h(X)_{MN}}. \] (25.43)

Differentiating with respect to \( h \) brings down a vertex operator for the graviton. In other words, the path integral for this action is the generating functional for the graviton \( S \)-matrix.

This observation suggests a general treatment for backgrounds for the massless particles

\[ I = \frac{1}{2\pi} \int d\tau \int_0^\pi d\sigma (g_{IJ} \partial_\alpha X^I + \epsilon^{\alpha\beta} B_{IJ} \partial_\alpha X^I \partial_\beta X^J). \] (25.44)

The corresponding path integral generates the \( S \)-matrix elements for both the graviton and the antisymmetric tensor field. But we would like to consider configurations which are not close to the flat metric with vanishing \( B_{MN} \). We can ask: what are acceptable backgrounds for string propagation? To answer this question, we need to remember that for the free string, conformal invariance was the crucial feature to the consistency of the picture. It was conformal invariance which guaranteed Lorentz invariance and unitarity. So we need to look for interacting two-dimensional field theories which are conformally invariant.

### 25.4.1 The beta function

Field theories of the type we have just encountered are called non-linear sigma models. In \( 1 + 1 \) dimensions, these are renormalizable theories: \( g_{IJ}, B_{IJ}, \) etc., are dimensionless. A priori, however, they are general functions of the fields, and there are an infinite – continuously infinite – set of possible couplings.

Physically, the statement that these theories must be conformally invariant is the statement that their beta functions must vanish. To get some feeling for what this means, let’s consider a special situation. Suppose that \( B_{IJ} \) vanishes, and that the metric is close to the flat space metric:

\[ g_{MN} = \eta_{MN} + \int d^D k h_{MN}(k) e^{ik \cdot x}. \] (25.45)

The action is then:

\[ I = \frac{1}{2\pi} \int d^2 \sigma \left( \eta_{IJ} \partial_\alpha X^I \partial^\alpha X^J + \sum_k h_{IJ}(k) e^{ik \cdot x} \partial_\alpha X^I \partial^\alpha X^J \right). \] (25.46)
We can treat the term involving $h$ as a perturbation. Working to second order, we have:

$$\left\{ \int d^2z_1(h_{\mu \nu}(k)e^{ik \cdot X(z_1)} \partial X(z_1)^{\mu} \partial X(z_1)^{\nu}) \times \int d^2z_2(h_{\rho \sigma}(k')e^{ik' \cdot X(z_2)} \partial X(z_2)^{\rho} \partial X(z_2)^{\sigma}) \right\}. \quad (25.47)$$

Let’s write this simply as:

$$\int d^2z \int d^2z' h_1 \mathcal{O}_1(z_1) h_2 \mathcal{O}_2(z_2). \quad (25.48)$$

Ultraviolet divergences will arise in this integral when $z_1 \to z_2$. In this limit, we can use the operator product expansion,

$$\mathcal{O}_1(z_1) \mathcal{O}_2(z_2) = \frac{c_{12j}}{|z_1 - z_2|^2} \mathcal{O}_j(z_2) + \cdots. \quad (25.49)$$

The integral over $z_2$ is ultraviolet divergent. If we cut it off at scale $\Lambda^{-1}$, we have the correction to the world sheet Lagrangian:

$$\int d^2z h_1 h_2 c_{12j} \mathcal{O}_j \ln(\Lambda). \quad (25.50)$$

There is another divergence associated with the couplings $h_1$ and $h_2$; this comes from normal ordering. In the case of the graviton vertex operator, if we simply expand the exponential factors and contract the $x$s, we obtain:

$$\int d^2z h_1(x) k^2 \ln(\Lambda). \quad (25.51)$$

Requiring, then, that the beta function for the coupling $h_1$ vanishes, gives:

$$k^2 h_1 + h_2 h_3 c_{123} = 0. \quad (25.52)$$

Recall, now, that $c_{ijk}$ is the three-point coupling for the three fields. So this is just the equation of motion, to quadratic order in the fields.

This result is general. At higher orders, one encounters divergences of two types. First, there are terms involving a single logarithm of the cutoff, times more powers of the fields. Second, there are terms involving higher powers of logarithms. The higher powers are, from a renormalization perspective, associated with iterations of lowest order divergences, and they are systematically subtracted off in computing the beta functions. From a space-time point of view, these correspond to the appearance of massless intermediate states, which must be subtracted off in constructing the effective action or equations of motion.

This procedure can be used to recover Einstein’s equations. A more elegant and efficient approach is to apply the background field method. For a general gravitational background, one can view $X$ as a fixed background, which solves the
two-dimensional equations of motion, and study fluctuations about it. For a suitable choice of coordinates, the metric is second order in the fluctuations. One can include in this analysis background antisymmetric tensor fields and a background dilaton. The antisymmetric tensor can be analyzed along the lines of our analysis of $h_{\mu\nu}$. The dilaton is more subtle. In our action above, we omitted one possible coupling: the two-dimensional curvature. The dilaton couples to the world sheet fields through:

$$\int d^2\sigma \Phi R^{(2)}. \tag{25.53}$$

The full analysis leads to the equations of motion:

$$\beta_{\mu\nu} = 0 = \alpha' R_{\mu\nu} + 2\alpha' \nabla_\mu \nabla_\nu \Phi - \frac{\alpha'}{4} H_{\mu\lambda\omega} H_{\nu}^{\lambda\omega} \tag{25.54}$$

$$\beta^B_{\mu\nu} = -\frac{\alpha'}{2} \nabla^\omega H_{o\mu\nu} + \alpha' \nabla^\omega \Phi H_{o\mu\nu} + O(\alpha')^2 \tag{25.55}$$

$$\beta^\Phi = \frac{D - 26}{6} - \frac{\alpha'}{2} \nabla^2 \Phi + \alpha' \nabla_\omega \Phi \nabla^{\omega} \Phi - \frac{\alpha'}{24} H_{\mu\nu\lambda} H_{\mu\nu\lambda}. \tag{25.56}$$

It is possible to extend these methods to describe quantum corrections to the equations, at least in the case of supersymmetric compactifications.

### 25.4.2 More general tori

As a first application, we consider the heterotic string theory in the case of more general tori.

For general metric and backgrounds for both the antisymmetric tensor and gauge fields, one obtains a somewhat more involved expression for the momenta. A particularly elegant way to derive this is to argue that constant background fields should effect only slow modes of the string. In the presence of background, constant metric and antisymmetric tensor fields, the action is:

$$I = \frac{1}{2\pi} \int d\tau d\sigma \int_0^\pi (g_{IJ} \partial_\alpha X^I \partial^\alpha X^J + \epsilon^{\alpha\beta} B_{IJ} \partial_\alpha X^I \partial_\beta X^J). \tag{25.57}$$

To realize the notion of slowly varying fields, one makes the Ansatz:

$$X^I = q^I(\tau) + 2\sigma m^I \tag{25.58}$$

where the second term allows for the possibility of winding. Substituting this back in the action and performing the integral over $\sigma$:

$$I = \int d\tau \left( \frac{1}{2} g_{IJ} \dot{q}^I \dot{q}^J + 2B_{IJ} \dot{q}^I m^J - 2g_{IJ} n^I n^J \right). \tag{25.59}$$
Now we can read off the canonical momenta:
\[ P_I = g_{IJ} \dot{q}^J + 2B_{IJ} m^J. \] (25.60)
In quantum mechanics, it is the canonical momenta which act by differentiation on wave functions, so it is the canonical momenta which must be quantized for a periodic system:
\[ P_I = n_I. \] (25.61)
In terms of \( q^I \), this gives:
\[ \dot{q}^I = g^{IJ} m_J - 2B^I_J n^J. \] (25.62)
Finally, integrating this equation and substituting back into \( X^I \):
\[ X^I = q^I + 2\sigma m^I + \tau (g^{IJ} n_J - 2B^I_J m^J). \] (25.63)
From this, we can read off the left- and right-moving momenta:
\[ p^I_L = m^I + \frac{1}{2} g^{IJ} n_J - g^{IJ} B_{JK} m^K \]
\[ p^I_R = -m^I + \frac{1}{2} g^{IJ} n_J - g^{IJ} B_{JK} m^K. \] (25.64)
Once again, \( p_L \cdot p'_L - p_R \cdot p'_R \) is an integer; the lattice, thought of as a Lorentzian lattice, is even and self-dual.
Including Wilson lines is slightly more subtle, because of their asymmetric coupling between left and right movers. For small \( A \), the modification is essentially what we guessed above. There is also a modification of the internal, \( E_8 \) charge lattice.

### 25.5 Bosonic formulation of the heterotic string
We have seen that in toroidal compactifications of string theory, new unbroken gauge symmetries can arise at particular radii. We have also seen that a toroidal compactification can be described by a lattice. So far, in describing the heterotic string, we have worked in what is known as the fermionic formulation. There is an alternative formulation, in which the 32 left-moving fermions are replaced by 16 left-moving bosons.
It is an old result that two-dimensional fermions are equivalent to bosons; more precisely, two real, left-moving fermions are equivalent to a single real boson, and vice versa. The correspondence, for a complex fermion, \( \lambda \), is:
\[ \lambda(z) = e^{i\phi(z)}, \] (25.65)
25.6 Orbifolds

where $\phi$ is a left-moving boson. The equal sign here is subtle; at finite volume, care is required with the zero modes, as we will see. To be convinced that this equivalence is plausible, consider correlation functions at infinite volume. From our previous analyses of two-dimensional Green functions, we have:

$$\langle \lambda(z)\lambda(w) \rangle = \langle e^{i\phi(z)} e^{i\phi(w)} \rangle \sim \frac{1}{z-w}. \quad (25.66)$$

This suggests that, say, in the case of the $SO(32)$ heterotic string, we can replace the 32 left-moving fermions by 16 left-moving bosons. Note that this means, loosely, that we have 26 left-moving coordinates, as in the bosonic string (but still only 10 right-moving bosons). At finite volume (i.e. $0 < \sigma < \pi$), we can write the usual mode expansions for these fields:

$$X^A_L = \frac{1}{2} p^A_L + \frac{i}{2} \sum_n \frac{1}{n} \tilde{\alpha}_n e^{-in(\tau+\sigma)}. \quad (25.67)$$

Now the $p_L$s are elements of the group lattice. Modular invariance requires that the lattice be even and self-dual. In 16 dimensions, there are two such lattices, those of $O(32)$ and $E_8 \times E_8$.

The bosonization of fermions which we have described here is useful for the right-moving fields as well and also for the fermions of the Type II theories. We have avoided discussing space-time supersymmetry in the RNS formalism because the fermion vertex operators and the supersymmetry generators must change the boundary conditions on two dimensional fields. But in this bosonized form, this problem is simpler. Once again, we have relations of the form

$$\psi_i \sim e^{i\phi_i}. \quad (25.68)$$

The $\phi$s live on a torus, whose “momenta” describe both N and RS states. Operators of the form $e^{i\phi}$ change NS to R states, i.e. they connect bosons to fermions. This connection allows construction of fermion vertex operators and the supersymmetry generators.

25.6 Orbifolds

Toroidal compactifications of string theory are simple; they involve free two-dimensional field theories. But they are also unrealistic. Even in the case of the heterotic string, they have far too much supersymmetry and their spectra are not chiral. There is a simple construction which reduces the amount of supersymmetry, yielding models with interesting gauge groups and a chiral structure. The corresponding world sheet theories are still free, so explicit computations are straightforward. These constructions are also interesting in other ways. They correspond
to particular submanifolds of the moduli space of larger classes of solutions. They exhibit interesting features like discrete symmetries and subtle cancellations of four-dimensional anomalies. At low orders, it is a simple matter to work out their low-energy effective actions. Through a combination of world sheet and space-time methods, one can understand their perturbative and in some cases non-perturbative dynamics.

In this chapter, we will work out one example in some detail. Other examples can be studied in a similar way. We will also mention some other free field constructions of interesting string solutions.

We start with a toroidal compactification on a particular lattice, a product of three tori as shown in Fig. 25.1. It is convenient to introduce complex coordinates,

$$ z^1 = x^1 + ix^2 \quad z^2 = x^3 + ix^4 \quad z^3 = x^5 + ix^6. $$

This lattice is invariant under a $Z_3$ symmetry

$$ z^i \rightarrow e^{2\pi i/3} z^i. $$

This can be seen by carefully examining the figure. The lattice vector $(1, 0)$, for example, in the original cartesian coordinates is rotated into the lattice vector $(-1/2, 1/\sqrt{2})$. This is related by translation by a lattice vector to $(1/2, 1/\sqrt{2})$.

Now we identify points under the symmetry, i.e. two points related by a symmetry transformation are considered to be the same point. The result is almost a manifold, but not quite. There are three points which are invariant under the symmetry. These are called “fixed points.” These are the points:

$$ (0, 0); \ (1/2, \sqrt{3}/2); \ (1, \sqrt{3}). $$

The geometry near each of these points is singular. If one parallel transports about, say the point at the origin, after $120^\circ$, one returns where one started. The space is said to have a deficit angle. It is as if there was an infinite amount of curvature located at each of the points. Such a space is called an “orbifold.”
In quantum mechanics, requiring such an identification of points under a symmetry means requiring that states be invariant under the quantum mechanical operator which implements the symmetry. Consider the various states of the original ten-dimensional theory. In the Type II theory, for example, in the NS–NS sector, we have the states, before making any identifications:

\[ \tilde{\psi}^\mu \frac{1}{2} \psi^\nu \frac{1}{2} |0\rangle, \quad \tilde{\psi}^j \frac{1}{2} \psi^\bar{j} \frac{1}{2} |0\rangle. \]

After the identification, the first set of states are invariant; the latter are not. These states all have simple interpretations. The first are the four dimensional graviton, antisymmetric tensor and dilaton. The second are the moduli of the torus. The parts symmetric under \( i \to \bar{j} \) correspond to the metric components in the original theory \( g_{ij} \). The antisymmetric parts correspond to the corresponding components of \( B_{ij} \).

The diagonal components, \( g_{ii} \), are easily understood. Changing slightly the value of these components correspond to changing the overall radius of the \( i \)th torus. This does not change the symmetry properties. The off-diagonal components, \( g_{12} \), etc., correspond to deformations which mix up the three planes, but leave a lattice with an overall \( Z_3 \) symmetry.

To understand what happens to the supersymmetries, focus on the gravitino. It is convenient to work in light cone gauge, and to decompose the spinors as we did earlier. To determine how the spinors transform under the \( Z_3 \), we need to decide how the state we called \( |0\rangle \) transforms under the symmetry. Consider a rotation, say in the 12 plane, by 120°. The rotation generator is:

\[ S_{12} = \frac{i}{4} (\gamma_1 \gamma_2 - \gamma_2 \gamma_1) = a^{1\dagger} a^1 + 1/2. \]

So the rotation of the state \( |0\rangle \), is described by

\[ e^{\frac{2\pi i}{3}} |0\rangle = e^{\frac{2\pi i}{3}} |0\rangle. \]

The transformations of the other states can then be read off from the transformation laws of the \( a^i \)'s:

\[ |0\rangle \to e^{-\frac{2\pi i}{3}} |0\rangle \quad a^\dagger |0\rangle \to e^{\frac{2\pi i}{3}} a^\dagger |0\rangle. \]

Now we have to be a bit more precise about the orbifold action. This is a product of \( Z_3 \)'s for each of the planes. But we see that acting on fermions, the separate transformations are \( Z_6 \)'s. In order that the group action be a sensible \( Z_3 \), we need to take, for example:

\[ Z^1 \to e^{\frac{2\pi i}{3}} Z^1 \quad Z^2 \to e^{\frac{2\pi i}{3}} Z^2 \quad Z^3 \to e^{\frac{4\pi i}{3}} Z^3. \]
With this definition, the fermion component $0 \leftrightarrow |0\rangle$ is invariant under the orbifold projection. The components $i \leftrightarrow a^\dagger |0\rangle$ are not.

We can label the gravitinos:

$$\psi^\mu_{0,\alpha} \quad \bar{\psi}^\mu_{0,\alpha} \quad \psi^\mu_{i,\alpha} \quad \bar{\psi}^\mu_{i,\alpha}.$$  \hspace{1cm} (25.78)

After the projection, instead of eight gravitinos, as in the toroidal case, there are only two; we have $N = 2$ supersymmetry in four dimensions.

In addition to projecting out states, we need to consider a new class of states. We can consider closed strings which sit at the fixed points. More precisely, in addition to the strict periodic boundary condition, we can consider strings which satisfy:

$$X^i(\sigma + \pi) = e^{\frac{2n}{3}} X^i(\sigma).$$ \hspace{1cm} (25.79)

These boundary conditions do not permit the usual bosonic zero modes. Instead, we have a mode expansion:

$$X^i = x^i_{(a)} + \frac{i}{2} \sum_n \left( \alpha^i_{n-\frac{1}{3}} e^{2i(n-\frac{1}{3})(\sigma-\tau)} + \bar{\alpha}^i_{n-\frac{1}{3}} e^{2i(n-\frac{1}{3})(\sigma+\tau)} \right).$$ \hspace{1cm} (25.80)

The mode numbers are now fractional; the absence of a momentum term indicates that the strings sit at the fixed points (labeled by $a$). In this case, there are 27 fixed points. For the fermions, we again have to distinguish Ramond and Neveu–Schwarz sectors. In the NS sectors, the fermions have modes which differ from integers by multiples of $1/2 - 1/3 = 1/6$:

$$\psi^i = \sum \psi^i_{n-\frac{1}{6}} e^{-2i(n-\frac{1}{6})(\tau-\sigma)}$$ \hspace{1cm} (25.81)

with a similar expansion for $\bar{\psi}$.

We can readily work out the normal ordering constant, using the formula we wrote earlier (Eq. (22.30)). We have, in the NS–NS sector:

$$a = 6 \times \frac{1}{4}(1/3 \times 2/3) - 6 \times \frac{1}{4}(1/6) \times (5/6) - 4 \times \frac{1}{4}(1/2) \times (1/2) = 0.$$ \hspace{1cm} (25.82)

So the ground state is massless in the twisted sectors. Again, because of $N = 2$ supersymmetry, there can be no potential for this field. So there is a modulus in each twisted sector. Unlike the moduli in the untwisted sector, this modulus does not correspond to simply changing the features of the torus which defines the orbifold. Instead, it represents a deformation which, from a space-time viewpoint, smooths out the orbifold singularity. The resulting smooth space is an example of a Calabi–Yau manifold, of the type we will discuss in the next chapter.

Let’s turn to the heterotic string theory on this orbifold. We will take the same projector on the spatial coordinates, $X^i$, as before. As a result, there is only one
Gravitino; the four-dimensional theory has $N = 1$ supersymmetry. The moduli are in one to one correspondence with the scalars of the NS–NS sector of the $N = 2$ theory: $g_{ij}, B_{ij}, \phi$. We can also make a projection on the world sheet gauge degrees of freedom. There are many possible choices of this gauge transformation; the principal restriction comes from the requirement of modular invariance. A particularly simple one is almost symmetrical between the left and right movers. In the fermionic formulation it works as follows. Take $E_8 \times E_8$ for definiteness. Of the 16 fermions in the first $E_8$ single out 6, and rewrite them in terms of three complex fermions, $\lambda^i$. Call the remaining ten fermions $\lambda^a$. Now, in the projection, require invariance under

$$Z^i \rightarrow e^{\frac{2\pi i}{3}} Z^i \quad \psi^i \rightarrow e^{\frac{2\pi i}{3}} \psi^i \quad \lambda^i \rightarrow e^{\frac{2\pi i}{3}} \lambda^i.$$  (25.83)

In the untwisted sector, this projection has no effect on the graviton or the moduli which we have identified previously. But consider the various gauge fields. In ten dimensions, these were vectors in the adjoint of the two $E_8$s and their fermionic partners. The fields with space-time indices in the internal dimensions now appear as four-dimensional scalars. In order that they be invariant under the full projection, it is necessary to choose their gauge quantum numbers appropriately. In the NS sector for each of the $E_8$s, the invariant states include the following.

1. A set of fields in the adjoint of $E_6$, $E_8$ and an $SU(3)$. Of these, an $O(10)$ subgroup of the $E_6$ is manifest in the NS–NS–NS sector, as well as an $O(16)$ subgroup of $E_8$. Correspondingly, the gauge bosons are:

$$\lambda^a_{-1/2} \lambda^b_{-1/2} \psi_\mu^{1/2} |0\rangle$$  (25.84)

in $O(10)$,

$$\lambda^A_{-1/2} \lambda^B_{-1/2} \psi_\mu^{1/2} |0\rangle$$  (25.85)

in $O(16)$, and, in $SU(3) \times U(1)$:

$$\lambda^I_{-1/2} \lambda^I_{-1/2} \psi_\mu^{1/2} |0\rangle.$$  (25.86)

Note that all of these states are invariant. The $U(1)$ is actually one of the $E_6$ generators. $E_6$ has an $O(10) \times U(1)$ subgroup under which the adjoint representation, which is 78-dimensional, decomposes as:

$$78 = 45_0 + 1_0 + 16_{-1/2} + 16_{1/2}.$$  (25.87)

The remaining $E_6$ gauge bosons are found in the R–NS–NS sector. The left-moving normal ordering constant vanishes. The ground states in this sector are spinors of $O(10)$, the 16 and $\bar{16}$ above. The 248-dimensional representation of the second $E_8$ is filled out as in the uncompactified theory.
Matter fields. These lie in the fundamental representation of $E_6$, the 27 under $O(10)$. The 27 decomposes as:

$$27 = 1 - 2 + 10_1 + 16_{-1/2}. \quad (25.88)$$

There are nine 10s in the untwisted sectors, corresponding to the states:

$$\lambda^a_{-1/2} \lambda^i_{-1/2} \psi^j_{-1/2} |0\rangle \quad (25.89)$$

Each of these is one real scalar; we can use the conjugate fields to form nine more real scalars, or eight complex scalars. There are nine singlets of charge $-2$:

$$\lambda^i_{-1/2} \lambda^j_{-1/2} \psi^k_{-1/2} |0\rangle. \quad (25.90)$$

The 16s come from the R–NS–NS sector.

So we have nine 27s from the twisted sectors, and no 27s; the theory is chiral.

Let’s turn now to the twisted sectors. In the Type II case we found moduli in each sector. Here we will find moduli, additional 27s, and more. We first need to compute the normal ordering constants. For the right movers, the calculation is exactly as in the Type II theory, and gives zero. For the left movers in the NS–NS sector, we have:

$$a = -\frac{8}{24} + (6/4) \times (1/3) \times (2/3) - \frac{16}{4} \times \left( -\frac{1}{24} + \frac{1}{4} \right)$$

$$+ \frac{16}{24} - \frac{10}{4} (1/4) - \frac{6}{4} \times (1/6) \times (5/6)$$

$$= -\frac{1}{2}, \quad (25.91)$$

where the first two terms comes from the bosons, the next two from the fermions in the unbroken $E_8$, and the last terms from the fermions in the broken $E_8$. So we can make massless states in a variety of ways.

1. We can have 10s of $O(10)$:

$$\lambda^a_{-1/2} |0\rangle_{\text{twist}}. \quad (25.92)$$

Note that $E_6$ invariance requires that this state have $U(1)$ charge +1.

2. Singlet of $O(10)$ with $U(1)$ charge $-2$:

$$\lambda^1_{-1/6} \lambda^2_{-1/6} \lambda^3_{-1/6} |0\rangle_{\text{twist}}. \quad (25.93)$$

Together with a set of spinorial states from the R–NS sector, this completes a 27 of $E_6$.

3. Moduli, other gauge singlets:

$$\alpha^i_{-1/3} \psi^j_{-1/6} |0\rangle. \quad (25.94)$$

If we contract the $i$ and $\bar{j}$ index, we find the analog of the twisted sector modulus we had in the Type II theory. The other states represent additional singlets.
All together, then, we have found $9 + 27 = 36$ copies of the 27 of $E_6$, and 36 moduli. Each 27 comfortably accommodates a generation of the standard model, plus an additional vector-like set of fields. So, while this example is hardly realistic, it is interesting: it predicts a particular number of Standard Model generations, plus additional fields. Whether variants of these ideas can lead to something more realistic is an important question, which we will postpone for the time being.

### 25.6.1 Discrete symmetries

One of the unappealing features of supersymmetric models as theories of nature is the need to postulate discrete symmetries in order to have a sensible phenomenology. This seems rather ad hoc. One of the features of the orbifold construction we just described is that a variety of discrete symmetries appear naturally. This phenomenon is common, as we will see, in string constructions. Here it is particularly easy to exhibit the symmetries.

We have, for simplicity, considered a particular form for the torus – a particular point in the moduli space, at which the six-dimensional torus is a product of three two-dimensional tori. But at this point (really a surface), there is a large symmetry. First, there is a separate $Z_3$ symmetry for each plane. (You can check that each plane in fact admits a $Z_6$ symmetry.) Because of the orbifold projection, one of these acts trivially on all states, but two are non-trivial. If we take the size of each of the three two-dimensional tori to be the same, we also have a permutation symmetry, $S_3$, among the tori.

The $Z_3$s are $R$ symmetries. We have already seen that the spinor with index 0 rotates by a phase, $e^{\frac{2\pi i}{6}}$, under the symmetry. By definition, this is an $R$ transformation. This has significant consequences for the low-energy theory, greatly restricting the form of the superpotential.

As an example of the far-reaching consequences of such symmetries, one can show that there are exact flat directions involving the matter fields. Consider the untwisted moduli. One can give expectation values to the $O(10)$ 10 and 1 in one multiplet in a way which respects supersymmetry. Specifically, consider the field, $\phi$, corresponding to

$$\phi = \lambda^a_{-1/2} \psi_{1/2}^\dagger |0\rangle$$  \hspace{1cm} (25.95)

and the corresponding singlet. Both of these are neutral under the rotation in the second plane. So one can not construct any superpotential term involving $\phi$ alone. One can give an expectation value to the singlet and to the 10 so as to cancel the $D$ terms for $E_6$. The main danger, then, is a superpotential term of the form:

$$W = \Psi \phi^2$$  \hspace{1cm} (25.96)
with $\Psi$ some other 27. This is $E_6$ invariant (in terms of $O(10)$ representations, it involves a product of a singlet and two 10s). But no such term is allowed by the discrete symmetries.

So this simple argument shows that the moduli space is even larger than we might have thought. Such symmetries, as they forbid not only certain dimension-four but also dimension-five operators, might also be important to understanding the problem of proton stability and other important phenomenological issues.

The model possesses other symmetries as well. There is $Z_3$ symmetry under which the twisted sector states transform but the untwisted sector states do not. We will not derive this here, but it is plausible, and can be shown readily if one constructs the vertex operators for the twisted states. Many of the discrete symmetries of the model are subgroups of the Lorentz symmetry of the original higher-dimensional theory. As such, they can probably be thought of as gauge symmetries. This is less obvious for other symmetries, but it is generally believed that the discrete symmetries of string theory all have this character. Searches for anomalies in discrete symmetries, for example, have yielded no examples.

One could ask: why would nature choose a point in the moduli space of some string theory at which there is an unbroken discrete symmetry? At the moment, our understanding of how to connect string theory to nature is not good enough to give a definite answer to this question, but, at the very least, such points are necessarily stationary points of the effective potential for the moduli; at the symmetric point, the symmetry forbids linear terms in the action for the charged moduli.

### 25.6.2 Modular invariance, interactions in orbifold constructions

As in our original string theory constructions, there seems much which is arbitrary in the choices we made above. We also did not spell out what are the appropriate GSO projectors. As for the simple ten-dimensional constructions, the possible GSO projections are constrained by modular invariance. We will leave for the exercises checking some particular cases, but the basic result is easy to state. One can project by any transformation, provided that it has sensible action on fermions and on spinor representations of the gauge group, and provided that one has “level matching” in all of the twisted sectors. This means that one must be able to construct an infinite tower of states in each sector. To understand the significance of this statement, consider a different choice of group action than that we considered above. Instead of twisting by $(1/3, 1/3, -2/3)$, project by $(1/3, -1/3, 0)$. In this case, for example, in the NS–NS–NS sector, the left-moving normal ordering constant is $-13/18$. As a result, one cannot construct any states in the twisted sector which satisfy the level matching condition.
There are other constructions of compactifications with $N = 1$ supersymmetry based on free fields. These include models based purely on free fermions. These models are believed equivalent to orbifold models in which one mods asymmetrically on the left- and right-moving fields. The latter, “asymmetric orbifold,” models are interesting in that they potentially have very few moduli. In order to have sensible, unbroken discrete symmetries acting on the left and right, the original lattice typically must sit at a self-dual point. So many moduli are fixed – they are projected out by the orbifold transformation. It is not difficult, in this way, to construct models where there are no moduli neutral under space-time symmetries, except for the dilaton.

25.7 Effective actions in four dimensions for orbifold models

While string theory provides a very explicit set of computational rules, at least for low orders of perturbation theory, these rules are complicated and rather cumbersome. Moreover, except in some special circumstances, we lack a non-perturbative formulation of the theory. Effective field theory methods have proven extremely useful in understanding the dynamics of string theory, both perturbative and non-perturbative. In this section, we will work out the effective action for the orbifold models introduced above. More precisely, we work out the Lagrangian for a subset of the fields, up to and including terms with two derivatives. Many of the features of these Lagrangians will be relevant to the more intricate Calabi–Yau compactifications we will encounter shortly.

In principle, to calculate the effective action, we should calculate the string $S$-matrix, and write an action for the massless fields which yields the same scattering amplitudes. Alternatively, we can calculate the equations of motion from the beta function and look for an action which reproduces these. But for low order terms in the derivative ($\alpha'$) expansion, for the fields in the untwisted sector, there is a simpler procedure. We know the form of the ten-dimensional effective action; we can simply truncate the theory to four dimensions. To do this, we start by setting all of the charged fields to zero (this includes the gauge fields). We also work at a point with a large discrete symmetry: $Z_3^3/Z_3 \times S_3$. We set all of the fields which transform under these symmetries to zero. This includes all of the moduli, except the overall size of the torus and its superpartners. We then write the metric as:

$$g_{ij}(x^\mu) = g_{ji}(x^\mu) = e^{\sigma(x^\mu)}\delta_{ij}. \quad (25.97)$$

With this parameterization, we are describing the size of the space with respect to a reference metric. We make a similar ansatz for the antisymmetric tensor:

$$b_{ij}(x^\mu) = -b_{ji}(x^\mu) = b(\sigma(x^\mu))\delta_{ij}. \quad (25.98)$$
We must keep also the four-dimensional metric components, \( g_{\mu\nu} \), the scalar field \( \phi \), and the antisymmetric tensor, \( B_{\mu\nu} \). Take all of them to be functions of \( x^\mu \), the uncompactified coordinates, only. Substituting these fields in the ten-dimensional Lagrangian, Eq. (24.8), the integral over the six internal coordinates is easy, since all fields are independent of the coordinates. One simply obtains \( e^{3\sigma(x)} \) from the \( \sqrt{g} \) factor. This is just the volume of the internal space, if \( \sigma \) is constant. There are additional factors of \( e^{-\sigma} \) coming from the factors of the inverse metric: one from the four-dimensional pieces of the Ricci curvature; one from the kinetic term for \( \phi \), and three from the \( H_{\mu\nu\rho} \) terms. The ten-dimensional curvature term also gives derivative terms in \( \sigma \). After a short computation, we obtain

\[
\mathcal{L} = -\frac{1}{2} e^{3\sigma} R^{(4)} - 3 e^{3\sigma} \partial_\mu \sigma \partial^\mu \sigma - \frac{9}{16} e^{3\sigma} \partial_\mu \phi \partial^\mu \phi / \phi^2 \\
- \frac{9}{2} e^{\sigma} \phi^{-3/2} \partial_\mu b \partial^\mu b - \frac{3}{4} \phi^{-3/2} H^{\mu\nu\rho} H_{\mu\nu\rho}.
\]  
(25.99)

It is customary to rescale the metric so that the Einstein term has the standard form:

\[
g_{\mu\nu} = e^{-3\sigma} g'_{\mu\nu}.
\]  
(25.100)

After this Weyl rescaling, the action becomes:

\[
\mathcal{L} = -\frac{1}{2} R^{(4)} - 3 \partial_\mu \sigma \partial^\mu \sigma - \frac{9}{16} (\partial^\mu \phi \partial_\mu \phi) / \phi^2 - \frac{3}{2} e^{-2\sigma} \phi^{-3/2} \partial_\mu b^2 - \frac{3}{4} \phi^{-3/2} e^{6\sigma} H^2_{\mu\nu\rho}.
\]  
(25.101)

It should be possible to cast this Lagrangian as a standard four-dimensional, \( N = 1 \) supergravity Lagrangian, with a particular Kahler potential. Having thrown away all but a few moduli, there is no superpotential. To determine the Kahler potential, we first note that, in four dimensions, an antisymmetric tensor field is equivalent to a scalar. This follows from counting degrees of freedom; with our usual rules, an antisymmetric tensor in four dimensions has only one degree of freedom. To make this explicit, one performs a “duality transformation” (the word is starting to seem a bit overused)

\[
\phi^{-3/2} e^{6\sigma} H_{\mu\nu\rho}(x) = \epsilon_{\mu\nu\rho\sigma} \partial^\sigma a(x).
\]  
(25.102)

The field \( a \) is often called the “model-independent axion,” because it couples like an axion and its features do not depend on the details of the compactification. Then we define two chiral superfields, whose scalar components are:

\[
S = e^{3\sigma} \phi^{-3/4} + 3i \sqrt{2} a
\]  
(25.103)

and

\[
T = e^{\sigma} \phi^{3/4} - i \sqrt{2} b.
\]  
(25.104)
Choosing the Kahler potential:

\[ K = - \ln(S + S^*) - 3 \ln(T + T^*) \]

reproduces all of the terms in Eq. (25.101). The reader may want to check all of the terms in this equation carefully, but at least it is good to make sure one understands how the \( \sigma \) and \( \phi \) dependences are reproduced.

Let’s now return to the ten-dimensional gauge field terms, Eq. (24.9). This will allow us to include the matter fields as well as the gauge fields. Rather than consider the full set of fields, we can restrict ourselves to the set which is invariant under each of the separate \( Z_3 \)s, combined with three separate \( Z_3 \)s in the gauge group \( (\lambda^i \rightarrow e^{\frac{2\pi i k}{3}} \lambda^i) \). This leaves us with three complex scalars, \( C^i \), corresponding to the states

\[ C^i \leftrightarrow \lambda_{-1/2}^i \lambda_{-1/2}^a \psi_{-1/2}^i |0\rangle \]  

\((i \text{ is not summed})\). From the point of view of ten dimensions, these are \( A_i^{ab} \). We also need to include the four-dimensional gauge fields, \( A_{\mu}^{ab} \). In this way we obtain the additional terms, after the Weyl rescaling:

\[ \mathcal{L}_{\text{gauge}} = -\frac{1}{4} \phi^{-3/4} e^{3\sigma} F_{\mu\nu}^2 - 3e^{-3/4} \phi F_{\mu} C^{*i} D^i C + \cdots \]  

(25.107)

This can still be put in the standard supergravity form. First, we need to remember that in the duality transformation, \( H_{\mu\nu\rho} \) now includes the Chern–Simons terms. Then it is necessary to modify the definition of \( T \) to include a contribution from the \( C \) fields:

\[ T = e^{\sigma} \phi^{3/4} - i \sqrt{2} b + C^{*i} C^i \]  

(25.108)

and to modify the Kahler potential:

\[ K = - \ln(S + S^*) - 3 \ln(T + T^* - C^* C). \]  

(25.109)

There is also a coupling of the field \( S \) to the gauge fields:

\[ \mathcal{L}_S = -\frac{1}{4} S W^2. \]  

(25.110)

This includes a coupling of \( \phi \) and \( \sigma \) to \( F_{\mu\nu}^2 \), already apparent in Eq. (24.9). The \( aF \tilde{F} \) coupling arises from the Chern–Simons term in Eq. (24.10). Recall that

\[ H_{\mu\nu\rho} = \delta_{[\mu} B_{\nu\rho]} - \omega_{\mu\nu\rho}. \]  

(25.111)

So \( \int d^4 x H^2 \), using the definition of \( a \) and integrating by parts, gives an \( aF \tilde{F} \) coupling. Finally, there is a superpotential cubic in the \( C \) fields.
25.7.1 Couplings and scales

It is worth pausing to note the connections between the couplings and scales in different dimensions. We’ll focus first on the heterotic string. We see from Eq. (25.110) that $S$ determines the gauge coupling, $S = 1/g^2$. This is as we would naively expect. The ten-dimensional gauge coupling is essentially $1/g_s^2$; when we reduce to four dimensions, the four-dimensional gauge fields correspond to modes which are constant on the internal manifold, so

$$\frac{1}{g_4^2} = \frac{1}{g_s^2} V M_s^6.$$  \hspace{1cm} (25.112)

In terms of the fields we defined above, $V = e^{3\sigma}$.

These simple formulas pose a serious problem for the application of weakly coupled heterotic string phenomenology. If we simply identify $S$ with the four-dimensional coupling, then the string coupling satisfies:

$$g_s^2 = g_4^2 V M_s^6.$$  \hspace{1cm} (25.113)

So we see that large volume, the limit in which an $\alpha'$ expansion is valid, conflicts with small $g_s$ if $g_4$ is fixed. We can also write a relation between the string scale and the Planck scale in four dimensions:

$$M_p^2 = M_s^8 V g_s^{-2}.$$  \hspace{1cm} (25.114)

Solving for $M_s$ and substituting in the previous expression, gives an expression for $g_s$ which is incompatible with weak coupling, if we assume that $V = M_G^{−6}$.

Later, we will sharpen this strong coupling problem, and consider possible solutions.

25.8 Non-supersymmetric compactifications

So far, we have considered supersymmetric compactifications. This is not necessary, but we will see that non-supersymmetric compactifications raise new conceptual and technical problems.

Perhaps the simplest non-supersymmetric compactification is Scherk–Schwarz compactification. Here one compactifies the theory (this can be Type I, Type II, or heterotic) on a torus. In one of the directions, say the ninth direction, one imposes the requirement that bosons should obey periodic boundary conditions, and fermions anti-periodic ones. One can describe this by taking the radius of the extra dimension to be $2 \times 2\pi R$, and performing a projection by

$$P = (-1)^F e^{(2\pi i) R p_9}.$$  \hspace{1cm} (25.115)
This projection eliminates, for example, the massless gravitinos; there is no supersymmetry, and there is no Bose–Fermi degeneracy in the spectrum. Indeed, in the simplest version, there are no massless fermions at all.

As a result, the usual Fermi–Bose cancellation of supersymmetry does not take place, and at one loop, there is a non-zero vacuum energy. More precisely, there is a potential for the classical modulus $R$. The calculation of this potential is just the Casimir calculation we encountered earlier. Only the massless ten-dimensional fields contribute; the massive string states give effects which are exponentially suppressed for large $R$. To see this, one can return to our earlier calculation with a massive state (one of the oscillator excitations of the string). Replacing the sum over integers by an integral in the complex plane and deforming the contour, as before, yields a term exponentially small in the mass. The detailed results depend on the particular model, but typically the potential is negative and goes to zero at large $R$. In other words, at one loop, the dynamics tends to drive the system to small $R$. It is not well understood how to study the system beyond one loop.

One can obtain non-supersymmetric theories in four dimensions in many other ways. For example, one can compactify the non-supersymmetric $O(16) \times O(16)$ heterotic theory on a torus (it can also, in some cases, be compactified on the Calabi–Yau spaces discussed in the next chapter). Again, one obtains a one loop potential for the moduli, and the theories are difficult to interpret at the quantum level. Compactifications of the Scherk–Schwarz theories and the non-supersymmetric theories are often related by $T$-dualities.

**Suggested reading**

An introduction to Kaluza–Klein theory prior to the development of string theory is provided in the text *Modern Kaluza–Klein Theories* by Appelquist *et al.* (1985). More thorough discussions of aspects of string compactification are provided by the texts of Green *et al.* (1987) and Polchinski (1998). Many of the original papers, particularly the orbifold papers, are highly readable; see, for example, Dixon *et al.* (1986). There are many topics here we have only touched on in this chapter. We gave an argument that vanishing of the beta function of the two-dimensional $\sigma$ model is equivalent to the equations of motion in space-time, but readers may wish to work through the background field analysis which leads to Einstein’s equations. This is described in Polchinski’s book and elsewhere. The bosonic formulation of the heterotic string is also well described there, but the original papers are quite readable (Gross *et al.* 1985, 1986). Bosonization and space-time supersymmetry in the RNS formulation are thoroughly discussed by Polchinski; a clear, and rather brief, introduction, is provided by Peskin’s 1996 TASI lectures (Peskin, 1997). The non-supersymmetric compactification described here was introduced by Rohm (1984).
25 Compactification of string theory I

Exercises

1. Derive the gauge terms in the Lagrangian of Eq. (25.7). You can do this by taking the metric to be flat.

2. Derive the scalar kinetic terms of Eq. (25.8). You can do this by taking the four-dimensional metric, at first, to be flat, and allowing only \( \sigma \) to be a function of \( x \).

3. Verify, by studying the OPEs of the vertex operators for the different massless fields, that the enhanced symmetry of the bosonic string at the point \( R = 1/\sqrt{2} \) is \( SU(2) \times SU(2) \). Explain why, in the heterotic string, the symmetry is only \( SU(2) \). What is the symmetry in the IIA theory?

4. For the orbifold model, work out the spectrum in the untwisted sectors in greater detail, paying particular attention to spinorial representations of the \( O \) groups, and to the space-time spinors. In particular, make sure you are clear that the 27s are chiral, i.e. all the states in 27s have one four-dimensional chirality, all of those in \( \overline{27} \) have the opposite chirality.

5. Derive the terms in Eq. (25.99) involving \( \partial \sigma^2 \).

6. Verify that the Kahler potential of Eq. (25.109) properly reproduces the kinetic terms of the matter fields.
Compactification of string theory II.
Calabi–Yau compactifications

So far, we have focussed on rather simple models, involving toroidal compactifications and their orbifold generalizations. But while by far the simplest, these turn out to be only a tiny subset of the possible manifolds on which to compactify string theories. A particularly interesting and rich set of geometries is provided by the Calabi–Yau manifolds. These are manifolds which are Ricci flat, $R_{MN} = 0$. Their interest arises in large part because these compactifications can preserve some subset of the full ten-dimensional supersymmetry. This is significant if one believes that low-energy supersymmetry has something to do with nature. It is also important at a purely theoretical level, since, as usual, supersymmetry provides a great deal of control over any analysis; at the same time, there is less supersymmetry than in the toroidal case, so a richer set of phenomena are possible.

This chapter is intended to provide an introduction to this subject. In the first section, we will provide some mathematical preliminaries. Unlike the toroidal or orbifold compactifications, it is not possible, in most instances, to provide explicit formulas for the underlying metric on the manifold and other quantities of interest. The six-dimensional Calabi–Yau spaces, for example, have no continuous isometries (symmetries), so at best one can construct the metrics by numerical methods. But it turns out to be possible to extract much important information without detailed knowledge of the metric from topological considerations. The machinery required to define these spaces and to extract at least some of this information includes algebraic geometry and cohomology theory, subjects not part of the training of most physicists. The following mathematical interlude provides a brief introduction to the necessary mathematics. There is much more in the suggested reading.

26.1 Mathematical preliminaries

Two notions are very useful for understanding Calabi–Yau spaces: differential forms and vector bundles. Differential forms have already appeared implicitly in our
discuss the compactification of IIA and IIB string theory. Start with an antisymmetric tensor field, $A_{i_1 i_2 \ldots i_n}$. Suppose that there is a gauge invariance:

$$A_{i_1 \ldots i_n} \rightarrow A_{i_1 \ldots i_n} + \frac{1}{n!} \left\{ \partial_{i_1} \Lambda_{i_2 \ldots i_n} - \partial_{i_2} \Lambda_{i_1 i_3 \ldots i_n} + \cdots (-1)^r \partial_{i_r} \Lambda_{i_1 \ldots i_{r-1} i_{r+1} \ldots i_n} \right\},$$  \hfill (26.1)

where $\Lambda$ is antisymmetric in all of its indices. We can write a shorthand for this:

$$\delta A = d\Lambda,$$  \hfill (26.2)

where $d\Lambda$ is the “exterior derivative.” Acting on an antisymmetric tensor of rank $p$, the exterior derivative produces a rank $p + 1$ antisymmetric tensor, $dH$:

$$dH_{i_1 \ldots i_{p+1}} = \left( \frac{1}{p+1} \right) \left[ \partial_{i_1} H_{i_2 \ldots i_{p+1}} - \partial_{i_2} H_{i_1 i_3 \ldots i_{p+1}} + \cdots \right].$$  \hfill (26.3)

We can think of this object more abstractly as follows. Antisymmetric tensors with $p$ indices we will call $p$-forms. A “basis” for the $p$-forms is provided by the antisymmetrized products of differentials:

$$dx^{i_1} \wedge dx^{i_2} \wedge \cdots \wedge dx^{i_p}.$$  \hfill (26.4)

We can then write:

$$H = \frac{1}{p!} H_{i_1 \ldots i_p} dx^{i_1} \wedge \cdots \wedge dx^{i_p}.$$  \hfill (26.5)

The product of two forms, $A$, $B$ is known as the wedge product, $A \wedge B$. If $A$ is an $n$-form and $B$ an $m$-form,

$$(A \wedge B)_{i_1 \ldots i_{n+m}} = \frac{n! m!}{(n+m)!} A_{i_1 \ldots i_n} B_{i_{n+1} \ldots i_{n+m}} + (-1)^p \text{permutations}$$  \hfill (26.6)

or, more compactly:

$$A \wedge B = \frac{1}{(n+m)!} A_{i_1 \ldots i_n} B_{i_{n+1} \ldots i_{n+m}} dx^1 \wedge \cdots \wedge dx^{n+m}.$$  \hfill (26.7)

In this language, the exterior derivative can be written as $d \wedge H$ or simply $dH$, where $d$ is thought of as a one form with components $d_i = \partial_i$.

It is important to practice with this notation, and some exercises are provided at the end of the chapter. One should check that

$$d^2 H = 0.$$  \hfill (26.8)

It is instructive to write electrodynamics in the language of forms. One should verify that the field strength tensor is a two form, which can be written as

$$F = dA.$$  \hfill (26.9)
26.1 Mathematical preliminaries

The homogeneous Maxwell’s equations (the Bianchi identities for the field strength) follow from \(d^2 = 0\),

\[dF = 0.\] (26.10)

Apart from multiplication and differentiation, there is another important operation denoted by \(*\), and called the Hodge star. In \(d\) dimensions, this takes a \(p\)-form to a \(d - p\)-form:

\[(*H)_{i_1...i_{d-p}} = \frac{1}{p!} \epsilon_{i_1...i_{d-p}} H^{i_1...i_{d-p+1}}_{i_{d-p+1}...i_d}.\] (26.11)

A particularly interesting object is \(*d\). For example, \(*d \wedge d\) is a \(d\)-form. But the components of a \(d\)-form are necessarily proportional to \(\epsilon_{i_1...i_d}\). With a little work, one can show that:

\[*(d \wedge d) = \partial^2.\] (26.12)

Using the \(*\) operation, we can write the action for a \(p\)-form field:

\[S = \frac{1}{2(p+1)!} \int *F \wedge F\] (26.13)

with \(F = dA\). This is clearly gauge-invariant. It is easy to check that this reproduces the standard action for electrodynamics.

For physics, we are particularly interested in zero modes of \(A\), i.e. field configurations that satisfy \(dA = 0\), but which are not simply gauge transformations, i.e. which cannot everywhere be written as

\[A = d\Lambda.\] (26.14)

A simple example of what is at issue is provided by a gauge field on a circle, \(0 \leq y \leq 2\pi R\). The one-form gauge field,

\[A_y = \partial_y \Lambda \quad \Lambda = c y\] (26.15)

is not a pure gauge transformation unless \(c = n/R\). In electrodynamics, for example, this corresponds to the fact that the Wilson line,

\[U = e^{i \int_0^{2\pi R} dy A_y}\] (26.16)

is gauge-invariant, and non-trivial, again, unless \(c = n/R\).

This suggests that we want to consider closed \(p\)-forms, \(\alpha\), which satisfy

\[d\alpha = 0\] (26.17)

but that we are not interested in exact forms,

\[\alpha = d\beta.\] (26.18)
More generally, we want to define an equivalence class, known as the cohomology class of $\alpha$. We will view $\alpha$ and $\alpha'$ as equivalent if

$$\alpha' = \alpha + d\beta,$$  \hspace{1cm} (26.19)

where $\beta$ is well defined everywhere on the manifold.

In general, for field configurations on a manifold $M$, the number of linearly independent zero modes is known as the Betti number, $b_p$. This number is related to the number of (basis) $p$-dimensional submanifolds which are not boundaries of $p+1$-dimensional surfaces. We won’t prove this, but we will at least make it plausible. Consider integration of a $p$-form, $\alpha$, over a $p$-dimensional submanifold, $\Sigma$:

$$\int_{\Sigma} \alpha_{i_1...i_p} d\Sigma^{i_1...i_p}. \hspace{1cm} (26.20)$$

By Stokes’ theorem, the integral of the exterior derivative of a $p-1$-form, $\beta$, over $\Sigma$, is related to the integral of $\beta$ over the boundary of $\Sigma$:

$$\int_{\Sigma} d\beta = \int_{\partial \Sigma} \beta. \hspace{1cm} (26.21)$$

If $\Sigma$ is compact, it has no boundary, so the integral of $d\beta = 0$.

Two $p$-forms are in the same cohomology class if

$$\int_{\Sigma} (\alpha - \alpha') = \int_{\Sigma} d\beta = \int_{\partial \Sigma} \beta = 0. \hspace{1cm} (26.22)$$

Note, as before, it is important in this expression that $\beta$ is defined throughout the manifold.

If we consider the structure of a massless chiral multiplet, we note that there are two scalars and a chiral fermion. In compactifications preserving $N = 1$ supersymmetry, modes of antisymmetric tensor fields which are annihilated by $d$ will correspond to massless scalars; supersymmetry guarantees that the other elements of the multiplet are also present. The suggested readings at the end of the chapter contain more detailed discussion of these issues, but it is not too hard to understand how the various states in terms of the forms annihilated by $d$. The other massless scalar arises because one can also choose the form so the Laplacian vanishes. The Dirac operator is closely related to differential forms on manifolds. This can be shown using the creation–annihilation operator construction of the Dirac matrices we have used in our discussion of orthogonal groups. One can exhibit in this way the required pairing.

With this machinery, we can define an important set of topological invariants of manifolds: characteristic classes. Consider a gauge field, $F$, $F = dA$. Note that $F$ is closed: $dF = 0$. Also, $F$ is said to be an element of $H_1(M, R)$, the second
cohomology group of the manifold \( M \) with real coefficients. The cohomology class of such two forms is known as the first Chern class.

If the manifold is topologically non-trivial, then if we consider a gauge field, it may not be possible to describe the field everywhere by a single, non-singular potential. This problem is familiar to us from the case of the Dirac monopole. Instead, in different regions, \( \alpha \) and \( \beta \), we have to use different potentials. \( A(\alpha) \), \( A(\beta) \).

In regions where \( \alpha \) and \( \beta \) overlap (transition regions), \( A(\alpha) \) and \( A(\beta) \) will be gauge transforms of one another,

\[
A(\alpha) = A(\beta) + \phi(\alpha\beta).
\]

(26.23)

Another set of gauge fields are said to be in the same topological class if

\[
\tilde{A}(\alpha) = \tilde{A}(\beta) + \phi(\alpha\beta)
\]

(26.24)

with the same transition function, \( \phi \). Now since the functions \( A \) and \( \tilde{A} \) are not uniquely defined everywhere, \( F = dA \) and \( \tilde{F} = d\tilde{A} \) are not in the trivial cohomology class, in general. On the other hand, \( F - \tilde{F} \) is, since the difference, \( A - \tilde{A} = B \) is well defined. So \( F - \tilde{F} = dB \), and \( F \) and \( \tilde{F} \) are in the same cohomology class. So the cohomology class of \( F \), the first Chern class, is a topological invariant.

There is a theorem that if the first Chern class is non-zero, one can always find a two-dimensional surface, \( \Sigma \), with the property:

\[
I(\Sigma) = \frac{1}{2\pi} \int_{\Sigma} F = \neq 0.
\]

(26.25)

Note that this is a kind of magnetic flux. By Dirac’s argument, \( I(\Sigma) \) is an integer. The first Chern class plays an important role in the theory of Calabi–Yau spaces.

These ideas can be generalized to complex spaces. Here we define, as we did for the orbifold, complex coordinates, \( z_i \) and \( \bar{z}_i \). We then define a \((p, q)\)-form \( \psi \) to be an object with \( p \) \( z_i \)-type indices and \( q \) \( \bar{z}_i \)-type indices. Note that \( \psi \) is totally antisymmetric in both types of indices. We can define two types of exterior derivatives, \( \partial \) and \( \bar{\partial} \), in the obvious way:

\[
\partial \psi_{a_1 a_2 \ldots a_p \bar{a}_1 \bar{a}_2 \ldots \bar{a}_q} = \frac{1}{p+1} \partial_{a_1} \psi_{a_2 \ldots a_p \bar{a}_1 \bar{a}_2 \ldots \bar{a}_q} + (-1)^p \text{ permutations}.
\]

(26.26)

Note that \( \partial^2 = 0 \); \( \bar{\partial} \) is defined similarly. In terms of these definitions,

\[
d = \partial + \bar{\partial}.
\]

(26.27)

These are known as the Dolbeault operators. We can then consider differential forms annihilated by these operators. The numbers of independent forms annihilated by the \( \partial \) and \( \bar{\partial} \) operators are known as the Hodge numbers, \( h^{p,q} \). Then, for example,
one has the Hodge decomposition:

\[ b_n = \sum_{p+q=n} h^{p,q}. \]  

(26.28)

Again, it is possible to choose these forms so that they are annihilated by the Laplacian.

26.2 Calabi–Yau spaces: constructions

We have already constructed a rather rich set of four-dimensional string theories. But they are only a small subset of what appears to be a vast set of possibilities. We saw, for example, that the orbifold compactifications give rise to moduli which describe states which are not orbifolds. A rich set of compactifications of string theory, of which the orbifolds we studied in the last chapter are special cases, are provided by the Calabi–Yau spaces. In this section, we introduce these.

Our strategy to construct solutions is to look for solutions of the ten-dimensional field equations. One can ask: why is this sensible? There are two answers. First, if we consider spaces in which the massless, ten-dimensional fields are slowly varying, it should be appropriate to integrate out the massive string modes and study the low-energy equations. A more serious question is: why can we simply look at the low-order equations? Even at the classical level, integrating out the massive states will lead to terms with arbitrary numbers of derivatives. This question is far more serious. If we solve the equations, say, involving two derivatives, we can try to find solutions of the terms up to four derivatives perturbatively. To do this, we expand the fields in modes of the lowest-order theory (e.g. eigenfunctions of the Laplace operator on the complex space). These are precisely the Kaluza–Klein modes. Calling these \( \phi_n \), plugging our lowest-order solution into the next order terms, we will obtain equations of the form:

\[ (\nabla^2 + m_n^2) \phi_n = \frac{\alpha'}{R^2} \Gamma_n. \]  

(26.29)

For \( m_n \neq 0 \), i.e. for the massive Kaluza–Klein modes, we simply obtain a small shift. But the massless modes are problematic. In the case of Calabi–Yau compactifications, it is supersymmetry which will come to our rescue. We will see that, for the massless modes, the tadpoles (\( \Gamma_n \)'s) vanish.

We begin with the Type II theory. Rather than examine the equations of motion, we look at the supersymmetry variations. In flat space four-dimensional theories, we are familiar with the idea that we find minima of the potential by setting the auxiliary fields to zero. We can phrase this in a different, seemingly more obscure way. We can find static solutions of the classical equations by requiring that the
supersymmetry variations of all of the fields vanish. That is, we require:
\[ \delta \psi = \epsilon F = 0 \quad \delta \lambda = \epsilon D = 0. \] (26.30)

We will try the same strategy. In Chapter 17, we introduced the essential elements required to understand spinors in a gravitational background (the reader may want to reread Section 17.6). To make things simple, we will look for solutions where the antisymmetric tensor vanishes and the dilaton is constant, so only the metric is spatially varying. Then the condition that there be a conserved supersymmetry becomes:
\[ \delta \psi_M = D_M \eta = 0. \] (26.31)

So \( \eta \) is covariantly constant. This means that under parallel transport around any closed curve, \( \eta \) returns to itself. As in gauge theories, the effect of parallel transport can be described in terms of Wilson lines, where now the Wilson line is written in terms of the spin connection, \( \omega \):
\[ U = P e^{\int \omega \cdot dx}. \] (26.32)

The fact that \( \eta \) is unchanged under any such transformation greatly restricts the form of \( \omega \). To see how this works, consider that in the ten-dimensional Lorentz group, there is an \( O(6) \) which acts on the compactified coordinates, as well as the four-dimensional Lorentz group acting on the Minkowski coordinates. The 16-component spinor in ten dimensions decomposes under these groups as
\[ \eta = (4, 2) + (\bar{4}, 2^*). \] (26.33)

By local Lorentz transformations, we can take the \((4, 2)\) to have the form (suppressing the four-dimensional spinor index):
\[ \eta = \begin{pmatrix} 0 \\ 0 \\ 0 \\ \eta_0 \end{pmatrix}. \] (26.34)

In order that this be invariant, we require that the spin connection lie in an \( SU(3) \) subgroup of \( O(6) \). The space is said to be a space of \( SU(3) \) holonomy.

In general, \( \omega \) is an \( O(6) \) matrix. Restricting to \( SU(3) \) is a strong constraint. Already \( U(3) \) holonomy requires that the manifold be complex. We encountered this already in the orbifold case, where we introduced three complex coordinates and their conjugates. There is no unique way to introduce the complex coordinates. The continuous set of choices will lead to a set of moduli of our solutions, known as the “complex structure moduli.” In addition, a manifold of \( U(3) \) holonomy is Kahler. This means that the metric can be derived from a function \( K(x^i, x^\bar{i}) \), the
Kahler potential, through:
\[ g_{ij} = \partial_i \partial_j K. \quad (26.35) \]

While proving that a manifold of \( U(3) \) holonomy must be Kahler is challenging, it is not hard to check that a Kahler manifold has \( U(3) \) holonomy. Some aspects of these manifolds are discussed in the exercises.

The Christoffel symbols and curvature for a Kahler manifold can be written in quite compact forms. (Verification of these formulas is left for the exercises.) The components of the affine connection (Christoffel symbols) are given by
\[ \Gamma^a_{bc} = g^{ad} \partial_b g_{cd} \quad \quad \Gamma^{\bar{a}}_{\bar{b}c} = g^{\bar{a}d} \partial_{\bar{b}} g_{\bar{d}c}. \quad (26.36) \]

As a result, the non-zero components of the Riemann tensor are:
\[ R^{\bar{a}}_{bcd} = \partial_c \Gamma^{\bar{a}}_{bd} \quad (26.37) \]

and the Ricci tensor is
\[ R_{bc} = -\partial_c \Gamma^{\bar{a}}_{\bar{b}a}. \quad (26.38) \]

Using
\[ \Gamma^{\bar{a}}_{\bar{b}a} = \partial_{\bar{b}} \ln \det g, \quad (26.39) \]

this can be further simplified:
\[ R_{bc} = -\partial_{\bar{b}} \partial_c \ln \det g. \quad (26.40) \]

Note that our result, Eq. (24.17), for the curvature of a two-dimensional Riemann surface is a special case of this.

The requirement that the metric have \( SU(3) \) holonomy has a dramatic consequence for the curvature: the Ricci tensor vanishes. This follows from our discussion of the spin connection as a gauge field for local Lorentz transformations. On a six (real)-dimensional Kahler manifold, we have seen that the spin connection is not an \( O(6) \) field, but rather a \( U(3) \) field (in four dimensions, it is a \( U(2) \) field, etc.). The \( U(1) \) part of the Riemann tensor is the trace over the Lorentz indices – the group indices, thinking of the Riemann tensor as a non-Abelian field strength. But this object is the Ricci tensor. So \( SU(3) \) holonomy requires that the Ricci tensor itself vanish everywhere on the manifold. For such a configuration, the lowest-order Einstein equation is automatically satisfied, \( R_{ij} = 0 \). The question which we would like to address is, given a Kahler manifold, is it possible to deform the Kahler potential so that the Ricci tensor vanishes. Clearly a necessary condition for this is that the integral,
\[ c_1 = \frac{1}{2\pi} \int \text{Tr} R \quad (26.41) \]
vanish. This quantity is the first Chern class, the topological invariant which we discussed earlier. It was Calabi who conjectured that the vanishing of the first Chern class for a manifold was a necessary and sufficient condition that the manifold admit a unique metric of $SU(3)$ holonomy. Yau later proved this conjecture. The spaces constructed in this way are the famous Calabi–Yau spaces. In general, while one can prove that such metrics exist, actually constructing them is a difficult numerical problem. Fortunately, many properties relevant to the low-energy behavior of string theory on these manifolds can be obtained from more limited, topological information.

It is worthwhile comparing this with our orbifold constructions. The orbifolds are everywhere flat. But the existence of a deficit angle associated with the fixed points means that there is actually a $\delta$-function curvature; this gives precisely the holonomy of these manifolds. If we decompose the spinors, as before, then as we transport them about the fixed points, the $i$ components pick up a phase, $e^{2\pi i/3}$, while the 0 components are invariant. Correspondingly, we found one unbroken supersymmetry.

When we discuss the heterotic theory on a Calabi–Yau space, we will have to choose values for the gauge fields as well. It will not be possible to simply set the gauge fields to zero. From the point of view of four dimensions, gauge fields with indices in the extra dimensions are like scalars, so this will result in breaking of some or all of the gauge symmetry. As we will see in Section 26.6.1, there are many possible choices for these fields, with distinct consequences for the structure of the low-energy theory. In an interesting subclass, some features of the heterotic theory are closely related to those of Type II on Calabi–Yau spaces.

26.3 The spectrum of Calabi–Yau compactifications

In both the Type II and heterotic cases, many features of the low-energy spectrum follow from general topological features of the manifold and do not depend on details of the metric. In the heterotic case, the number of generations (minus the number of anti-generations) is a topological invariant. Suppose that we have some number of generations for some choice of metric. If we now make smooth, continuous changes in the metric, the massless spectrum can change as generations and anti-generations pair to gain mass or become massless. In other words, a mass term in an effective action can pass through zero, but the net number of generations cannot change. In some cases, other features of the spectrum are similarly invariant. So while it is difficult to write down explicit metrics for manifolds of $SU(3)$ holonomy, it is possible to determine many important features of the low-energy theory from basic topological features of the manifold.
In the Type II theory, the numbers of hypermultiplets and vector multiplets are separately topological. They do not pair up as one moves about on the moduli space; the $N = 2$ supersymmetry insures that if a field is massless at one point in the moduli space, it is massless at all points. Even more dramatic is the fact that massless states found in the lowest order of the $\alpha'$ expansion are exactly massless. So it is enough to study the lowest-order supergravity equations of motion to count massless particles.

The important non-zero Hodge numbers are $h^{2,1}$ and $h^{1,1}$. In the IIA theory, there are $h^{1,1}$ vector multiplets and $h^{2,1}$ hyper-multiplets. In the IIB theory, this is reversed. In the heterotic case, the $(2, 1)$ forms will correspond, effectively to generations, the $(1, 1)$-forms to anti-generations.

The counting of massless fields is not difficult to understand. Since we have taken the antisymmetric tensor fields and fermions to vanish in the background, the equations for these fields are particularly simple. Consider the antisymmetric tensor, $B_{\mu \nu}$. On a complex manifold, as we explained earlier, there are $h^{1,1}$ $(1, 1)$ forms, $b^{(a)}_{i,\bar{j}}$ and $h^{2,1}$ $(2, 1)$-forms annihilated by the operators $\partial$ and $\bar{\partial}$. Since the corresponding three-index field strengths, $H = dB$, vanish, there is no energy cost to giving a constant expectation value to the associated four-dimensional fields; they correspond to massless scalars in four dimensions. The fields connected to the $(1, 1)$-forms, $b_{i\bar{i}}$, are easy to describe. In addition to the antisymmetric tensor, there is also a massless perturbation of the metric:

$$i g_{i\bar{i}}(x, y) = \phi(x) b_{i\bar{i}}(y). \quad (26.42)$$

Here $x$ refers to the ordinary four-dimensional Minkowski coordinates, and $y$ refers to the compactified coordinates. Similarly, in the IIA theory, one can find a massless gauge field, rounding out the bosonic components of the vector multiplet. This comes from the three-index Ramond field,

$$C_{\mu i\bar{i}}(x, y) = A_\mu(x) b_{i\bar{i}}(y). \quad (26.43)$$

We will leave for the reader the problem of working out the structure of the hypermultiplets in terms of the $(2, 1)$-forms, and also determining the pairings in the IIB case.

One $(1, 1)$-form which is always present is the Kahler form:

$$b^K_{i\bar{i}} = i g_{i\bar{i}}; \ b_{i\bar{i}} = -i g_{i\bar{i}}. \quad (26.44)$$

This satisfies

$$\partial b^K = \bar{\partial} b^K = 0 \quad (26.45)$$

because $g_{i\bar{i}} = \partial_i \bar{\partial}_{\bar{i}} K$. The real scalar which sits in the multiplet with $b^K$ is just the metric itself. The corresponding massless field is the radius of the compact
space:

\[ g_{i,i}(x^\mu, z^i) = R^2(x^\mu)g_{i,i}(z); \quad B_{i,i}(x^\mu, z^i) = b(x^\mu)b_{i,i}(z). \quad (26.46) \]

That the field is massless is no surprise; the condition \( R_{i\bar{i}} = 0 \) is not changed under an overall rescaling of the metric so the vev is undetermined.

### 26.4 World sheet description of Calabi–Yau compactification

So far, we have described compactification of string theory in terms of ten-dimensional space-time. This analysis makes sense if the radius of the compactified space is large compared to the string length, \( \ell_s \). We can also formulate these questions in world sheet terms. This provides a complementary way to understand many features of the compactified theory. This is useful for at least two reasons. First, it provides tools to ask what happens when the compactification radius is of order the string scale or smaller. Second, there are some features of the spectrum and interactions which are more readily accessible in this framework.

In the Type II theory, the non-linear sigma model which describes compactification on a Calabi–Yau space has some striking features. First, in the absence of background antisymmetric tensor fields, it is left–right symmetric. Second, there are two left-moving and two right-moving supersymmetries on the world sheet, as opposed to the one left-moving and one right-moving supersymmetry of a general configuration. This can be usefully understood in a number of ways. In the light cone gauge, one can work with the covariantly constant spinor \( \eta \) and its conjugate, \( \bar{\eta} \), to construct two left-moving and two right-moving supersymmetry generators, both in the sense of the world sheet and in space-time. We have already seen this in the case of orbifold constructions. There, in the light cone gauge, we have eight left-moving and eight right-moving supersymmetry generators, before the orbifold projection. We can organize these in terms of their transformation properties under the \( SU(3) \times U(1) \) holonomy group. For both the left and right movers, there are triplets, \( Q_i \), anti-triplets, \( \bar{Q}_{\bar{i}} \), and singlets, \( Q_0 \) and \( \bar{Q}_0 \). The triplets and anti-triplets are charged under the \( U(1) \); the singlets are not. The orbifold projection eliminates the triplets. The two singlets survive.

In a purely world sheet description, non-linear sigma models described by a Kahler metric automatically have two left-moving and two right-moving supersymmetries. To describe these, we can introduce a superspace with four Grassmann coordinates, two left movers and two right movers: \( \theta^A_+ \) and \( \bar{\theta}^A \). This superspace can be thought of as the truncation of \( N = 1 \) supersymmetry in four dimensions. We can define, as in four dimensions, operators \( D_\alpha \) and \( \bar{d}_\dot{\alpha} \), and left- and right-moving chiral fields annihilated by the \( \bar{d}s \). Correspondingly, we can define chiral left- and
right-moving fields:

\[ X^i_+(z, \theta) = x^i(z) + \theta^A \psi^i_A(z) + \text{auxiliary field} \quad (26.47) \]

and similarly for \( X^i_- \). In terms of these fields, we can write the action of the conformal field theory as:

\[
\int d^2 \sigma \int d^2 \theta_+ d^2 \theta_- K(X, \bar{X}). \quad (26.48)
\]

Integrating over the \( \theta \)s, the bosonic terms are just \( \int d^2 \sigma g_{ii} \partial_a x^i \partial^a x^i \), with \( g_{ii} \) the Kahler metric.

The superconformal algebra, in these backgrounds, is enlarged to what is referred to as the \( N = 2 \) superconformal algebra (one such algebra for the left movers, one for the right movers). In addition to the stress tensor and the two supercurrents, this algebra contains a \( U(1) \) current. The supersymmetry generators can be constructed by the Noether procedure. They can also be guessed by taking the generators in a flat background, and making the expressions covariant:

\[
G^+ = g_{ii} DX^i \bar{\psi} \quad G^- = g_{ii} DX^i \psi. \quad (26.49)
\]

These have opposite charge under the \( U(1) \) current (an \( R \) current) constructed from the fermions:

\[
j(z) = \bar{\psi}(z) \psi(z) \quad (26.50)
\]

and a similar current for the left movers. The full algebra is:

\[
T(z) G^\pm(0) \approx \frac{3}{2z^2} G^\pm(0) + \frac{1}{z} \partial G^\pm(0)
\]

\[
T(z) j(0) \approx \frac{1}{z^2} j(0) + \frac{1}{z} \partial j(0)
\]

\[
j(z) G^\pm(0) \approx \pm \frac{1}{z} G^\pm(0). \quad (26.51)
\]

These equations say that \( G \) has dimension 3/2, while \( j \) has dimension 1, and \( G^\pm \) have \( U(1) \) charges plus and minus one. The central charge appears in the relations:

\[
G^+(z) G^-(0) \approx \frac{2c}{3z^3} + \frac{2}{z^2} j(0) + \frac{2}{b} T(0) + \frac{1}{z} \partial j(0)
\]

\[
G^+(z) G^+(0) \approx 0
\]

\[
j(z) j(0) \approx \frac{c}{3z^2}. \quad (26.52)
\]

The non-linear sigma models appropriate to heterotic compactifications on Calabi–Yau spaces have a number of interesting features. We will see that, for a particular choice of gauge fields, the world sheet theory which describes the heterotic
compactification is identical to that of the Type II theory. Thus, again, they have two left-moving and two right-moving supersymmetries \((2, 2)\) supersymmetry. The fact that the world sheet theories of the two different string theories are the same allows us to argue, as we will below, that Calabi–Yau spaces are solutions of the full, non-perturbative string equations of motion. But this observation also tells us about interesting features of the spectrum.

To understand the spectrum, it is helpful to ask, first, what is a vertex operator from the perspective of the two-dimensional conformal field theory? The answer is that a vertex operator is a marginal deformation of the theory, a perturbation of dimension 2 \((1, 1)\), in terms of the left- and right-moving Virasoro algebras. The standard way to compute the dimensions of operators is to treat them as perturbations, and calculate, for example, the beta function of the perturbation. For marginal operators, the beta function vanishes to first order. Moduli correspond to “exactly marginal deformations” of the theory. For these, the beta functions vanish to all orders in the perturbation (and non-perturbatively), corresponding to the fact that the theory, even for a finite perturbation, is conformal.

The existence of moduli means that there is a multiparameter set of conformal field theories. Varying the action with respect to the parameters yields operators which are exactly marginal. In this way, we have the two-dimensional version of the correspondence between moduli and massless fields.

An example of a modulus is the radius of the complex space. The lowest-order equation for the metric is invariant under an overall scaling of lengths. But this is not obviously true of the higher-order corrections. For Type II theories, the space-time supersymmetry guarantees that there is no potential for the moduli, so the sigma model is a good conformal field theory, suitable for heterotic string compactification. On the heterotic side, we can also give a more direct world-sheet argument. Here \(R^{-2}\) is the coupling constant of the \(\sigma\) model. In other words, writing the metric as \(R^2\) times a reference metric of order the string scale, \(R^2\) scales out of the Lagrangian. We know that the lowest-order beta function equation is the same as the field theory equation. It is trivially independent of \(R^2\), since it is a one-loop effect. For higher orders, there is a non-renormalization theorem. This follows from a combined world sheet, space-time argument. The superpartner of fluctuations in the radius is the fluctuation of the antisymmetric tensor field, \(b_{i\bar{i}} = i g_{i\bar{i}}\). The associated vertex operator (term in the action) is a total derivative on the world sheet at zero momentum. It is perhaps easiest to see this by writing the vertex operator at zero momentum in the form:

\[
V_b = b_{MN} \epsilon^{\alpha\beta} \partial_\alpha X^M \partial_\beta X^N \\
= \partial_M \partial_N K \epsilon^{\alpha\beta} \partial_\alpha X^M \partial_\beta X^N \\
= \partial_\alpha [\epsilon^{\alpha\beta} \partial_\beta X^M \partial_M K].
\]

(26.53)
So \( b \) decouples at zero momentum. Because \( b \) is in a supermultiplet with \( R^2 \), this means that the superpotential, which is a holomorphic function of the superfields, is independent of \( R^2 \).

Actually, this statement is not precisely correct, because \( K \) is not single-valued. In perturbation theory, it is true, since one is not sensitive to the global structure of the manifold (in perturbation theory, all fluctuations are small). Non-perturbatively, one can encounter instantons in the world sheet theory. A more detailed analysis is required to determine whether there are corrections to the superpotential. In left–right symmetric compactifications of the heterotic string, those with two left-moving and two right-moving supersymmetries ((2, 2) models), a study of fermion zero modes in the presence of the instanton shows that no superpotential for the moduli is generated; this is consistent with the expectations from the Type II theory. For compactifications with two right-moving but no left-moving supersymmetries ((2, 0) models), corrections can be generated, though in some cases intricate cancellations still prevent the appearance of a potential for the moduli. These two classes of models are phenomenologically quite distinct, as we will see shortly.

### 26.5 An example: the quintic in \( \mathbb{CP}^4 \)

It is helpful to have a concrete example of a Kahler manifold with \( c_1 = 0 \), on which we know one can construct a metric of \( SU(3) \) holonomy. We have previously encountered the complex projective spaces in \( N \) dimensions, \( \mathbb{CP}^N \). These are defined as the spaces with \( N + 1 \) complex coordinates, \( Z_a \), with the identification \( Z_a \to \lambda Z_a \), for any complex number \( \lambda \). We have written down a Kahler potential on this space:

\[
K = \ln \left( 1 + \sum_{a=1}^{N} Z_a \bar{Z}_a \right).
\]  

Any complex submanifold of a Kahler manifold is also a Kahler manifold; one can simply take the Kahler potential to be the Kahler potential of the full manifold evaluated on the submanifold. To obtain a manifold with three complex dimensions, we can start with \( \mathbb{CP}^4 \), and write an equation for the vanishing of a polynomial, \( P(Z) \). The polynomial should be homogeneous, in order that it have a sensible action in \( \mathbb{CP}^N \). It turns out that it should satisfy other conditions. Its gradient should vanish, at most, at the origin (which is not a point in \( \mathbb{CP}^N \)). In order that the first Chern class vanish, it should be quintic. We will give an argument for this shortly.

The simplest (most symmetric) possibility is:

\[
P = Z_1^5 + Z_2^5 + Z_3^5 + Z_4^5 + Z_5^5 = 0,
\]  

(26.55)
but there are obviously many more. We can deform this polynomial by adding other quintic polynomials. These correspond to varying the complex structure. Since each deformation produces another solution of the string equations, each deformation corresponds to a modulus, the “complex structure moduli.” Associated with each of these deformations is a form of type (2, 1), which we will not attempt to construct here.

Before listing the deformations, note that not every deformation corresponds to a change of the physical situation – and thus to a massless particle. Holomorphic changes of the coordinates which are non-singular and invertible do not change the complex structure. The transformation

$$Z_i \rightarrow Z_i + \epsilon^{ij} Z_j$$

(26.56)

is well-defined in CP$^4$. As a consequence, deformations such as $Z_1^4 Z_2$ are not physical. So we can list the possible deformations:

$$Z_1^3 Z_2^2 \ldots; Z_1^2 Z_2^3 \ldots; Z_1^2 Z_2^2 Z_3 \ldots; Z_1 Z_2 Z_3 Z_4 \ldots; Z_1 Z_2 Z_3 Z_4 Z_5.$$  

(26.57)

All together there are 101 possible deformations of the polynomial, corresponding to $h_{2,1} = 101$. In this example, there is only one Kahler modulus, the overall radius of the compact space.

We can understand heuristically why the first Chern class vanishes in a way which we will help us understand other features of these manifolds. A characteristic feature of the Calabi–Yau spaces is the existence of a covariantly constant 3-form, $\omega_{ijk}$. The existence of this form follows from the existence of the covariantly constant spinor, $\eta$:

$$\omega_{ijk} = \bar{\eta} \Gamma_{[ijk]} \eta.$$  

(26.58)

Working in terms of the creation–annihilation operator basis for the $\Gamma$'s, one sees that $\omega$ is holomorphic. The $\Gamma$'s can be defined so that the $\Gamma_i$ matrices annihilate $\eta$. Then, because of the complete antisymmetrization, only components of $\omega$ with $i, j, k$ indices are non-vanishing. In the space defined by the vanishing of a quintic polynomial in CP$^4$, we can show that there exists a holomorphic three-form which is everywhere non-vanishing. Calling $x^i = Z_i/Z_5$, $i = 1, \ldots, 4$:

$$\omega = dx^1 \wedge dx^2 \wedge dx^3 \left( \frac{\partial P}{\partial x^4} \right)^{-1}. $$  

(26.59)

One can show that this expression does not depend on singling out a particular coordinate, and that it is not singular at the points where the derivative vanishes, provided that the polynomial $P$ is quintic and that the gradient of $P$ vanishes only at the origin. The existence of such a form can be shown to be equivalent to the vanishing of the first Chern class.
26.6 Calabi–Yau compactification of the heterotic string at weak coupling

Much effort has been devoted to the study of compactifications of the weakly coupled heterotic string on Calabi–Yau spaces. These theories have many of the features of the Standard Model. They also allow one to consider many of the questions of beyond the Standard Model physics. Before beginning an analysis of these models, it is worth listing some of the points that we can address in this framework.

1. Low-energy supersymmetry: solutions of the classical equations of the heterotic string theory on Calabi–Yau spaces exist. They have \( N = 1 \) supersymmetry. Supersymmetry, as in field theory, is unbroken to all orders of perturbation theory, but may be broken non-perturbatively.

2. Low-energy gauge groups: the simplest constructions have gauge group \( E_8 \times E_6 \), broken perhaps by Wilson lines, which preserve the rank of the gauge group. But many models have a moduli space in which the gauge group is broken to precisely that of the Standard Model.

3. Generations: the number of generations is typically determined in terms of topological features of the underlying manifold.

4. Massless particles, not protected by symmetries: various massless states arise, which are not protected by chiral symmetries. This is precisely what we want in order to understand the presence of light Higgs fields in supersymmetric theories. We know that if such fields are present in the low-energy field theory, they are protected from gaining large masses by non-renormalization theorems. In field theory, the vanishing of such mass terms appears mysterious; in these string constructions, it is automatic. Such states could play the role of Higgs fields in supersymmetric models. In other words, the \( \mu \) problem of ordinary supersymmetric field theories is readily solved in this framework.

5. Unification of couplings: the string theories we are studying are not grand unified theories in the conventional sense. There is no energy scale at which these compactifications appear as four-dimensional theories with a single unbroken gauge group. Yet, generically, couplings are unified. These last two points, which we will see are easy to understand in terms of the microscopic structure of string theory, are quite surprising from a low-energy point of view. They have sometimes been referred to as “string miracles.”

6. Continuous and discrete symmetries: it is easy to prove that, for these compactifications (and for weak-coupling heterotic models in general) there are no continuous global symmetries; all continuous symmetries must be gauge symmetries. Discrete symmetries, on the other hand, proliferate, and might play the role of \( R \)-parity or lead to other interesting phenomena. These discrete symmetries are typically gauge symmetries, in the sense that they are residual symmetries left over after the breaking of continuous gauge symmetries.

We will also see that there are a number of problems with these models, which illustrate some of the basic difficulties in developing a string phenomenology.
(1) There are too many of them. While there are models with three generations (many), there are models with hundreds of generations, with non-standard gauge groups and the like.
(2) The problem of moduli: non-perturbatively, moduli can acquire potentials, but they typically vanish in various asymptotic regimes. Simple general arguments indicate that stable, supersymmetry-breaking minima, if they exist, must be in regions which are inherently strongly coupled, in the sense that no weak coupling approximation is available.
(3) The problem of the cosmological constant: this is closely related to the previous one. In many instances moduli potentials can be calculated. For any given value of the moduli, the size of these potentials is scaled as one would expect by the scale of supersymmetry breaking. As a result, even if strongly coupled, stable minima exist, it is not clear why the cosmological constant should be small at these points.

We will not offer a solution to these problems in this chapter, but will explore at least one proposed answer known as the “landscape” in the concluding chapter.

26.6.1 Features of Calabi–Yau compactifications of the heterotic string

In the previous section, we asserted that, in suitable backgrounds, the world sheet conformal field theory which describes the heterotic string is the same as that which describes the Type II theory. Here, we describe compactifications of the heterotic string theory in more detail.

To construct solutions, we still look for solutions which preserve a space-time supersymmetry. Again, we require the supersymmetry variation of the gravitino to vanish, giving $D_\mu \eta = 0$, so once more we need a covariantly constant spinor. There is now an equation for the variation of the ten-dimensional gaugino, as well:

$$\delta \lambda \propto \Gamma^{ij} F_{ij} \eta.$$  \hfill (26.60)

One strategy, then, to find solutions which preserve $N = 1$ supersymmetry is to require that $F_{ij} \Gamma^{ij}$ is an $SU(3)$ matrix. There is a simple Ansatz which achieves this. Both $E_8$ and $O(32)$ have $SU(3)$ subgroups:

$$SU(3) \times E_6 \times E_8 \subset E_8 \times E_8 \quad SU(3) \times O(26) \subset O(32) .$$  \hfill (26.61)

On the Calabi–Yau space, the spin connection is an $SU(3)$ valued field, so take the gauge field to be a field in one of these $SU(3)$ subgroups. Then for gauge generators not in $SU(3)$, Eq. (26.60) is automatically satisfied. For those in $SU(3)$, the condition is mathematically identical to that for the gravitinos, and is again satisfied.

This Ansatz satisfies another condition. We put the antisymmetric tensor field $B$ to zero, but, because of the Chern–Simons terms, this does not by itself guarantee that the field strength $H$ is zero. But with this Ansatz, the Chern–Simons terms for
the gauge and gravitational fields are identical. As a quick check, note that
\[ dH = \text{Tr} R \wedge R - \text{Tr} F \wedge F, \]  
and these terms clearly cancel.

This establishes that this is a solution of the equations of motion to lowest order in the $\alpha'$ expansion. But there is another way to see this, which will allow us to establish, as we did for the Type II theory, that this is an exact solution, perturbatively and non-perturbatively. If we write the non-linear sigma model which describes the heterotic string in this background, it is identical to that for the Type II theory. To see this, as in the orbifold case, we divide the left-moving gauge fermions into three sets. First, there are the fermions in the “other” $E_8$, which are not affected by the background gauge field and remain free, $\lambda^A, A = 1, \ldots, 16$. In the first $E_8$, 10 fermions, $\lambda^a, a = 1, \ldots, 10$ (transforming as a vector in the $O(10)$ subgroup of $E_6$) are also free. The remaining six interacting fermions can be grouped, like the left-moving coordinates, into three complex fermions, $\lambda^i$ and $\lambda^\bar{i}$. These fermions interact in precisely the same way as the left-moving fermions in the Type II theory. This can be seen by writing the action of the Type II fermions in terms of the vierbein and spin structure, rather than the metric and the Christoffel connection.

We see from this that the moduli of the Type II theory are also moduli of the heterotic theory. Actually, we knew this had to be, since we know that each of these conformal field theories, on the Type II side, is a good conformal field theory for the heterotic theory. But we can also see this pairing more directly in the language of vertex operators. Here it is somewhat more convenient to work in the RNS picture. The vertex operators correspond to small deformations of the background in the directions of the moduli. In the Type II theory, they are built from right-moving fields, $\partial X^i$ and $\psi^i$, and left-moving fields, $\bar{\partial} \tilde{X}^i, \tilde{\psi}^i$. In the heterotic case we can trade $\tilde{\psi}^i$ with $\lambda^i$. Since the action for the $\lambda^i$’s is the same as for the $\tilde{\psi}^i$’s, the dimensions of the vertex operators are exactly the same. This does not preclude the existence of additional moduli on the heterotic side, and we will see that there are typically additional moduli in these compactifications.

While all moduli of the Type II theory are moduli of the heterotic theory, not all heterotic moduli correspond to states of the Type II theory. Vertex operators for moduli which preserve only two right-moving supersymmetries $(2, 0)$ are not suitable vertex operators for the Type II theory. The moduli we are considering here are distinguished because they preserve the two left-moving world sheet supersymmetries, and we will refer to these as Type II moduli. Perhaps more interesting, though, than the pairing of moduli is is a pairing of the Type II moduli with matter fields. The moduli associated with $(2, 1)$-forms are paired with 27s of $E_6$; $(1, 1)$ moduli with $\overline{27}$s. This is most readily seen in the language of vertex operators, using the world sheet superconformal symmetry. The vertex operators for the Type II theory are the highest components of the corresponding superconformal multiplets with
respect to both left- and right-moving supersymmetries. In superspace, they are the $\theta_+^2 \theta_-^2$ components of operators of the form:

$$f(X^i, \bar{X}^i). \quad (26.63)$$

The $\theta_+^2 \theta_-^2$ component has dimension $(1/2, 1)$. We can form an operator of dimension $(1, 1)$ by multiplying by $\lambda^a$, one of the free fermions. This operator is not highest weight with respect to the left-moving $N = 2$ algebra, but this is not a problem; this symmetry is not a gauge symmetry on the world sheet, but simply an “accident” of our choice of background field. It is highest weight with respect to the left-moving Virasoro algebra, which is all that matters.

We already observed this pairing in the $Z_3$ orbifold model, which is a special case of the Calabi–Yau construction. In the untwisted sector, the vertex operators for the moduli took the form, on the left:

$$\bar{\partial} X^i, \quad (26.64)$$

while for the 27s they took the form:

$$\lambda^a \lambda^i. \quad (26.65)$$

The supersymmetry transformation of the latter operator changes $\lambda^i$ to $\bar{\partial} X^i$.

The distinction between 27s and $\bar{27}$s is readily understood. In the Type II case, we can distinguish two types of moduli, depending on their charges under the $U(1)$ within the left-moving $N = 2$ algebra. In the orbifold context some vertex operators involve $\bar{\partial} X^i$, some $\bar{\partial} X^i$. In the heterotic case, the world sheet $U(1)$ symmetry corresponds to the $U(1)$ subgroup of $E_6$ in the decomposition $O(10) \times U(1) \subset E_6$. This $U(1)$ charge is precisely what distinguishes the 10s, for example, in the 27 and $\bar{27}$. In the Type II case, this distinction corresponds to the distinction between $(2, 1)$ and $(1, 1)$ moduli, so we obtain precisely the pairing we described above (note that what one calls a 27 and a $\bar{27}$ is a matter of convention; if one adopts the opposite convention, the identification is reversed).

This result holds everywhere in the moduli space; since the number of moduli of each type does not change as one moves in the moduli space, the number of 27s and $\bar{27}$s does not change. This is a surprising result. One might have thought that, in a complicated construction such as this, 27 and $\bar{27}$s would, whenever possible, pair to gain mass. But this is not the case. This is precisely the sort of phenomena one needs to understand light Higgs particles in supersymmetric theories. We will see shortly how this works in a more detailed model.

### 26.6.2 Gauge groups: symmetry breaking

So far, the heterotic models we are considering have group $E_8 \times E_6$. If we are to describe the Standard Model, we need to be able to break this symmetry. We have
seen in the case of toroidal compactifications that gauge symmetries can be broken by expectation values of gauge fields with indices in compactified dimensions. Stated in a more gauge-invariant fashion, these are non-trivial expectation values for Wilson lines. In the Calabi–Yau case, the same is possible.

Let’s consider a specific example: the quintic in CP\(^4\), with vanishing of the polynomial:

\[
Z_1^5 + Z_2^5 + Z_3^5 + Z_4^5 + Z_5^5 = 0. \tag{26.66}
\]

The corresponding Calabi–Yau manifold, we saw, has 101 27s and one \(\overline{27}\). This polynomial has a variety of symmetries. As for the torus, we can use these to project out states and simplify the spectrum. Consider, for example, the symmetry:

\[
Z_i \rightarrow \alpha^i Z_i \quad \alpha = e^{2\pi i/5}. \tag{26.67}
\]

This is a symmetry of the polynomial. It is somewhat different than the orbifold symmetries we have discussed, since, as the reader can check it acts without fixed points. Mathematicians call such a symmetry “freely acting.” For physics, it means that if we mod out the Calabi–Yau by this symmetry, while it is still necessary to include twisted sectors, the twisted strings have mass of order \(R\), the Calabi–Yau radius, and there are no light states in these sectors if \(R\) is large.

We can readily classify the states invariant under this symmetry. Among the moduli, there are 21 \(h_{2,1}\) fields, associated with polynomials such as \(Z_1^3Z_3Z_4\) and \(Z_1Z_2Z_3Z_4 Z_5\). The Kahler modulus (overall radius) is also invariant under this transformation, and so survives the projection. The corresponding Euler number is 40, 1/5 the Euler number of the covering space. There are, as well, 21 27s of \(E_6\) and one \(\overline{27}\). Further symmetries can be used to reduce the number of generations to as few as four.

But what interests us here is obtaining smaller gauge groups. We can define the \(Z_5\) to include a transformation in \(E_6\). This is equivalent to the presence of a Wilson line on the manifold. An interesting way to do this is to consider a somewhat different decomposition of \(E_6\) than we have considered up to now:

\[
SU(3) \times SU(3) \times SU(3) \subset E_6. \tag{26.68}
\]

An example of a Wilson line in this product of \(SU(3)\)s is:

\[
U = \begin{pmatrix}
1 & 0 & 0 \\
0 & 1 & 0 \\
0 & 0 & 1
\end{pmatrix} \times \begin{pmatrix}
\alpha & 0 & 0 \\
0 & \alpha & 0 \\
0 & 0 & \alpha
\end{pmatrix} \times \begin{pmatrix}
\alpha & 0 & 0 \\
0 & \alpha & 0 \\
0 & 0 & \alpha^3
\end{pmatrix}. \tag{26.69}
\]

This breaks \(E_6\) to \(SU(3) \times SU(2) \times SU(2) \times U(1)^2\).
26.6.3 Massless Higgs fields, or the $\mu$ problem

When we mod out so as to reduce the gauge symmetry, we also alter the spectrum. We have seen that we greatly reduce the number of moduli and the number of generations. The presence of the Wilson lines also disrupts the left–right symmetry of the model. As a result, the pairing of moduli and matter fields is no longer quite so simple.

In the presence of the Wilson line, one still obtains 20 complete $E_6$ generations. If one thinks, loosely, of some of the massless fields “gaining” mass, elements of the 27 and $\overline{27}$s must pair up to gain mass. More precisely, in this modding out procedure, states disappear, but they must disappear in pairs. But one also obtains some incomplete multiplets, where paired states do not disappear. Consider the $\overline{27}$. This is invariant under the original $Z_5$s, so any state which survives must be invariant under the Wilson line. Using the decomposition of the 27 under $SU(3)^3$:

$$27 = (3, 1, \bar{3}) + (\bar{3}, 3, 1) + (1, \bar{3}, 3).$$  \hspace{1cm} (26.70)

So we obtain $Z_5$ singlets from only the third multiplet. These form a $(1, 2, 2)$ under $SU(3) \times SU(2) \times SU(2)$, as well as a singlet. There is a corresponding pair of states from the $27$s. This is the sort of multiplet we would like to understand the presence of light Higgs particles in supersymmetric models: massless states, at tree level, which arise, from a low-energy point of view, more or less by accident.

26.6.4 Continuous global symmetries

In the heterotic string theory, there are no continuous global symmetries. We won’t give the formal proof here, but the basic argument is not hard to understand. If there is a global symmetry, it should be a symmetry of the world sheet theory. In this way, we are guaranteed that vertex operators can be chosen to have well defined transformation properties, and so the $S$-matrix will transform properly. The global symmetry will be associated with a world sheet current. This current can be decomposed into left- and right-moving pieces. But from any left-moving current, we can build a gauge boson vertex operator, so the symmetry is necessarily a gauge symmetry. Right-moving currents will not commute with the world sheet supersymmetry generators, and will not have well-defined action on states (in the BRST language, they do not commute with the BRST operator). So they are not symmetries in space-time.

This argument also indicates that there are no global symmetries in the Type II theories. This is in accord with our expectation that global symmetries are unlikely to arise in a theory of quantum gravity.
26.6.5 Discrete symmetries

When we studied orbifold models, we found discrete symmetries existed in a subset of vacua on the full moduli space. This is also the case for the Calabi–Yau manifold constructed from the vanishing of a quintic polynomial in CP⁴. Such symmetries turn out to be quite common.

The quintic polynomial, \( P = \sum Z^5_i \), exhibits a set of \( Z_5 \) symmetries:

\[
Z_i \rightarrow \alpha^{k_i} Z_i \quad \alpha = e^{\frac{2\pi i}{5}}.
\] (26.71)

An overall phase rotation of all of the \( Z_i \)'s has no effect in CP⁴, so the symmetry here is \( Z_4^5 \). There is also a permutation symmetry, \( S_5 \). This symmetry group is a subgroup of the \( O(6) \) symmetry which would act on six non-compact, flat dimensions. We can thus think of these symmetries as discrete gauge transformations. So their existence in a theory of gravity is not surprising.

We would like to know if these symmetries are \( R \)-symmetries or not. We can address this by asking their effect on the covariantly constant spinor, \( \eta \). This is more challenging to do than in the orbifold context, since we do not have quite such explicit expressions. It is simplest to look at the covariantly constant 3-form. We already gave a construction:

\[
\omega = dx^1 \wedge dx^2 \wedge dx^3 \left( \frac{\partial P}{\partial x^4} \right)^{-1}
\] (26.72)

with \( x^i = Z_i/Z_5 \). This construction treats the coordinates asymmetrically, but, as we explained, \( \omega \) is symmetric among the coordinates. Note that \( \omega \) transforms essentially like \( \eta^2 \), i.e. like \( \theta^2 \). So symmetries under which \( \omega \) transforms non-trivially are \( R \)-symmetries, and \( W \) transforms like \( \omega \).

Consider, first, the \( Z_5 \) transformations of the separate \( Z_i \)'s. We can read off immediately how \( \omega \) transforms under transformations of the first three; the other two follow by symmetry. So

\[
\omega \rightarrow \alpha^{\sum k_i}.
\] (26.73)

Similarly, under those \( S_5 \) transformation which permute \( Z_1, Z_2, Z_3 \), we can see how \( \omega \) transforms. If the permutation is odd, \( \omega \) changes sign. So again, the general \( S_5 \) transformation is an \( R \)-symmetry.

Turning on the various complex structure moduli typically breaks some or all of this symmetry. For example, if we turn on the modulus associated with the polynomial

\[
\prod_{1 \leq i < j \leq 5} (z_i z_j)
\] (26.74)
we break the $Z_5^4$ symmetry down to a subgroup satisfying $\sum k_i = 0 \mod 5$. This group is $Z_5^3$, but it is a non-$R$-symmetry, in light of the transformation law of $\omega$. An expectation value for this field clearly preserves the permutation symmetry.

Similarly, turning on, say, $aZ_1^3Z_2 + bZ_1^2Z_2^2$ breaks the symmetries acting on $Z_1$ and $Z_2$, as well as some of the permutation symmetry. Turning on enough fields breaks all of the symmetry.

One might ask why one should be interested in points or surfaces in the moduli space which preserve a discrete symmetry, when in the bulk of the space there is no symmetry. This question is closely related to the question: what sorts of dynamics might fix the moduli? This is a subject which we will deal with extensively later, but for which we will provide no definitive resolution. But even without understanding this dynamics, there is a simple reason to suspect that points in the moduli space with symmetries might be singled out by dynamics. Imagine that we somehow manage to compute an effective potential for the moduli, arising, perhaps, due to some non-perturbative string effects. Symmetry points are necessarily stationary points of this effective potential. There is, of course, no guarantee that they are minima of the potential, but they are certainly of interest as candidates for string ground states.

There are, as we have seen, certain facts of nature which suggest that discrete symmetries might play some role in extensions of the Standard Model, including proton decay and dark matter.

### 26.6.6 Further symmetry breaking: the Standard Model gauge group

The Wilson line mechanism, as we have described it, provides a path to reduce the gauge symmetry from $E_6 \times E_8$, but leaves the rank untouched. We can hope to reduce the gauge symmetry further by giving expectation values to some of the matter fields. Ideally, these expectation values would be large. The presence of other gauge groups (as well as unwanted matter multiplets) can spoil the prediction of coupling unification, and lead to severe difficulties with proton decay and other rare processes. We are led, then, to ask if we can consider more general states, in which the spin connection is not equal to the gauge connection, and the rank is reduced.

This is a complex subject, which has only been partially explored. At lowest order in the $\alpha'$ expansion, there are such flat directions. They are not left–right symmetric, and while, in order that they exhibit space-time supersymmetry, they have two right-moving supersymmetries, they have only one left-moving supersymmetry. So they are not suitable backgrounds for Type II theories, and one cannot argue as easily as

---

1 Non-Abelian discrete symmetries offer possibilities for reducing the rank, but we will not explore these here.
for the standard embedding that these \((0, 2)\) configurations are solutions of exact classical string equations. They are still subject to perturbative non-renormalization theorems in \(\alpha'\). But detailed study of instanton amplitudes is required to determine if these flat directions are lifted non-perturbatively, i.e. by corrections of the form \(e^{-R^{2}\alpha'}\).

There are, however, a class of vacua with Standard Model gauge group which can be found by symmetry arguments, much as we found additional flat directions in the \(Z_3\) orbifold model. Consider, again, the quintic in \(\text{CP}^5\), with the symmetric polynomial. We can find flat directions of the \(D\) terms by taking \(27 = \overline{27}\). More precisely, starting with the \(E_6\) decomposition into \(O(10)\) representations,

\[
27 = 10^1 + 1_{-2} + 16_{-1/2},
\]

we can give expectation values to the singlets in the \(\overline{27}\) and one of the \(27s\). These are also flat directions of the \(F\) terms. For example, consider the \(27\) corresponding to the polynomial \(Z_1Z_2Z_3Z_4Z_5\). The product, \(\overline{27} 27\) is invariant under all of the discrete \(R\)-symmetries; no terms of the form \((\overline{27} 27)^n\) can appear in the superpotential. So this direction is exactly flat (terms of the form \(27^3\), \(\overline{27}^3\) cannot lift these directions either). In combination with Wilson lines, these flat directions readily break to the \(SU(3) \times SU(2) \times U(1)\) group of the Standard Model.

26.6.7 Gauge coupling unification

One of the striking successes of low-energy supersymmetry is its prediction of unification. Within the context of grand unification – where the gauge group of the Standard Model is unified in a simple group at a scale \(M_{\text{GUT}}\) – the fact that the couplings unify is readily understood. In the context of the compactifications considered here, it is not immediately obvious why this should be the case. In the case of symmetry breaking by Wilson lines, for example, the compactification scale and the scale of the symmetry breaking are of the same order. So there is no energy scale where one has a unified, four-dimensional effective theory.

In the weakly coupled heterotic string, however, the couplings do unify under rather broad conditions. In the case of Wilson line breaking this can be understood immediately in field-theoretic terms. The effect of the Wilson line is to eliminate states from the \(E_6\) unified theory, but at tree level no couplings are altered. So the couplings of all groups emerging from \(E_6\) are the same. Perhaps more surprising is the fact that the \(E_6\) and \(E_8\) couplings are the same. This can be seen by considering the vertex operators for the gauge bosons in each group. In both cases, the vertex operators are constructed in terms of free two-dimensional fields, which obey the same algebra (in the unbroken subgroup) as in the flat space theory. So, for example,
the operator product expansions of these gauge boson vertex operators are unaltered. There are constructions where unification does not hold. These involve replacing the two-dimensional fermions with a current algebra with a different central extension.

In the (2, 1) flat directions considered above, we can give an argument based on the low-energy field theory that the couplings remain unified as one moves out along the flat direction. A change in the coupling requires that there be a coupling of this modulus to the gauge fields. But at the classical level, we know that there are no such couplings, because any such coupling would violate the axion shift symmetry. This symmetry is unaffected by the expectation value of these moduli.

When we come to consider strongly coupled strings, the problem of coupling unification will be more complicated. It will be less clear in what sense unification is generic. Whether this is a problem for the theory, or a clue, is a question for the student to ponder.

### 26.6.8 Calculating the parameters of the low-energy Lagrangian

As we have explained, string theory is a theory without fundamental dimensionless parameters. On the other hand, the structure of the low-energy theory, we now see, depends on discrete choices: which Calabi–Yau, orbifold, etc., in how many dimensions, with how much supersymmetry, with which Wilson lines, and continuous dynamical quantities, the moduli. For any given choice, at least classically, it should be a straightforward problem to calculate the parameters of the low-energy theory.

It is easy to calculate the four-dimensional gauge couplings in terms of the ten-dimensional dilaton and the radius. We have already seen how this works for simple compactifications, and this carries over directly to the Calabi–Yau case, since the vertex operators for the gauge fields are constructed in terms of two-dimensional fields, as in the orbifold or toroidal case.

The cosmological constant is another interesting quantity in the low-energy theory. At the classical level in the Calabi–Yau compactifications, it vanishes. This can be understood in a variety of ways. First, if we examine the solution of the ten-dimensional equations of motion, we see that since the Ricci tensor vanishes, there is no cosmological term. Second, in the two-dimensional conformal field theory, the cosmological constant would give rise to a tadpole for the dilaton, but this is forbidden by conformal invariance. Ultimately, the absence of a cosmological constant is inherent in the form of the solution: we assumed that four dimensions are flat. We will see later that this is not necessary: string theory admits AdS spaces, as well as Minkowski spaces, as classical solutions.

From the perspective of trying to understand the Standard Model, a particularly important set of parameters are the Yukawa couplings. These can certainly be computed in the string theory. In principle, we should construct the vertex operators
for the appropriate matter fields, and then construct the required OPE coefficients or suitable scattering matrices. In practice, this can often be short-circuited. In the orbifold models, for example, in the untwisted sectors we can read off the Yukawa couplings by dimensional reduction of the ten-dimensional Lagrangian. The scalar fields are components of the original ten-dimensional gauge fields, $A_i$. Similarly the fermions are components of the ten-dimensional gauginos. In the orbifold theory, alternatively, it is not difficult to construct the vertex operators and to compute the required OPE coefficients.

In the Calabi–Yau case, we have seen that, in the $\alpha'$ expansion, the superpotential is independent of $R$. So one can work at very large radius, and pick off the leading contribution. To actually do the computation, one can construct the zero modes of the scalar and spinor fields, and substitute in the Lagrangian. A priori, one might expect that this would be quite difficult, given that one does not have an explicit formula for the metric. But it turns out that the Yukawa couplings have a topological significance, and their values can be inferred by general reasoning. We will not have use for explicit formulas here, but it is important to be aware of their existence.

### 26.6.9 Other perturbative heterotic string constructions

The quintic is just one of a large class of Calabi–Yau models which can be constructed. The exact number is not actually known. It is not even known, with certainty, whether the number of Calabi–Yau vacua is finite or infinite.

So while we will not assess here the size of this space, there is clearly a large class of string solutions with gauge group identical to that of the Standard Model. These theories have varying numbers of generations, including both orbifold (or free fermion) models and Calabi–Yau constructions with three. There are many models with groups, numbers of generations, and other features radically different than those of the Standard Model. Still, it is remarkable how easily we have obtained models which accord with some of our speculations for Physics Beyond the Standard Model. We have found low-energy supersymmetry, coupling unification, light Higgs particles, discrete symmetries which can potentially suppress proton decay and give rise to a stable dark matter candidate, all in a framework where we can imagine that real calculations are possible.

In subsequent chapters, we will turn to the problems of actually turning these observations and discoveries into a real theory which we can confront with experiment.

### Suggested reading

Volume 2 of Green et al. (1987) provides a comprehensive introduction to Calabi–Yau compactification, and I have borrowed heavily from their presentation. Weakly
coupled string models with three generations have been constructed in the context of Calabi–Yau compactification; their phenomenology is considered by Greene et al. (1987). Models based on free fermions have been constructed by Faraggi (1999). We will encounter non-perturbative constructions in Chapter 28. At special points in their moduli spaces, some Calabi–Yau spaces can be described in terms of solvable conformal field theories. This program was initiated by Gepner (1987), and is described at some length by Polchinski (1998). A very accessible description, including computations of physically interesting couplings, appears in Distler and Greene (1988).

**Exercises**

1. Write the field strength of electrodynamics as a two-form, and express its gauge invariance in the language of forms. Verify that $dF = 0$ is the Bianchi identity (the homogeneous Maxwell equations).

2. Show that for a Kahler manifold, the non-vanishing components of the affine connection (Christoffel symbols) are given by Eq. (26.36). Then show that the non-zero components of the Riemann tensor are given by Eq. (26.37) and verify Eq. (26.38). Derive Eq. (26.40) by noting that
   \[
   \Gamma^a_{\bar{b} \bar{a}} = \partial_{\bar{b}} \ln \det g. 
   \]  
   Show that our result for the two-dimensional curvature of a Riemann surface is a special case of this.

3. For a flat, two-dimensional torus, introduce complex coordinates and verify that the bosonic and fermionic terms are just those of the free string action. You can take $K = X^\dagger X$ for this case.

4. Write out the action of the heterotic string propagating in the Calabi–Yau background with spin connection equal to the gauge connection in some detail. Determine the form of the vertex operators for the 27 and \( \bar{27} \) fields, in the RNS formulation (you can limit yourself to the NS–NS sector).

5. Exhibit a combination of Wilson lines and $SU(5)$ singlet expectation values which break the gauge group to that of the Standard Model in the case of the quintic in CP\(_4\).
In previous chapters, we have seen that string theory at the classical level shows promise of describing the Standard Model, and can realize at least one scenario for physics beyond: low-energy supersymmetry. But there are many puzzles, most importantly the existence of moduli and the related question of the cosmological constant. At tree level, in the Calabi–Yau solutions, the cosmological constant vanishes. But whether this holds in perturbation theory and beyond requires understanding of the quantum theory.

In studying string theory, we have certain tools:

1. weak coupling expansions,
2. long-wavelength (low-momentum, $\alpha'$) expansions.

We have exploited both of these techniques up to this point. In analyzing string spectra, we have worked in a weak coupling limit. There are corrections to the masses and couplings, for example, in string perturbation theory, and most of the states that we have studied have finite lifetimes. At weak coupling, these effects are small, but at strong coupling, the theories presumably look dramatically different.

In asserting that Calabi–Yau vacua are solutions of the string equations, we used both types of expansions. We wrote the string equations both in lowest order in the string coupling, and also with the fewest number of derivatives (two). Even at weak coupling and in the derivative expansion, we can ask whether Calabi–Yau spaces are actually solutions of the string equations, both classically and quantum mechanically. For example, we have seen that, at lowest order in both expansions, there are typically many massless particles. We might expect tadpoles to appear for these fields, both in the $\alpha'$ and in loops. There is in general no guarantee we can find a sensible solution by simply perturbing the original one.

Yet there are many cases where we can make exact statements. In both Type II and heterotic string theories, we can often show that Calabi–Yau vacua correspond
to exact solutions of the classical string equations. We can also show that they are
good vacua – there are no tadpoles for massless fields – to all orders of the string per-
turbation expansion. More dramatically, we can sometimes show that these vacua
are good, non-perturbative states of the theory. This is perhaps surprising, since
we lack a suitable non-perturbative formulation in which to address this question
directly. The key to this magic is supersymmetry. In the framework of quantum
field theory, we have already seen that supersymmetry gives a great deal of control
over dynamics, both perturbative and non-perturbative. We were able to prove a va-
riety of non-renormalization theorems from very simple starting points. The more
supersymmetry, the more we could establish. The same is true in string theory.
We can easily prove a variety of non-renormalization theorems for string perturba-
tion theory. We can show that with $N = 1$ supersymmetry in four dimensions, the
superpotential is not renormalized from its tree level form in perturbation theory;
the gauge coupling functions are not renormalized beyond one loop. These same
considerations indicate the sorts of non-perturbative corrections which can (and do)
arise. In theories with more supersymmetries, one can prove stronger statements:
the superpotential is not renormalized at all, and there are strong constraints on the
kinetic terms. These sorts of results will be important when we try to understand
weak–strong coupling dualities.

27.1 Non-renormalization theorems

In each of the superstring theories one can prove a variety of non-renormalization
theorems. Consider, first, the case of ten dimensions. At the level of two derivative
terms, the actions with $N = 1$ or $N = 2$ supersymmetry (16 or 32 supercharges)
are unique. So, **perturbatively and non-perturbatively, there is no renormalization.**
This is a variant of our discussion in four-dimensional field theories. If we di-
mensionally reduce the Type II theories on a six-dimensional torus, we obtain a
four-dimensional theory with 32 supercharges ($N = 8$ in four dimensions); if we
reduce the heterotic theory, we obtain a theory with $N = 4$ supersymmetry in four
dimensions (16 supercharges). In either case, the supersymmetry is enough to pre-
vent corrections to either the potential or the kinetic terms, not only perturbatively
but non-perturbatively.

These are quite striking results. From this we learn that the question of whether
the universe is four-dimensional or not, or whether it has, say, four or eight su-
persymmetries, or none, is not simply a dynamical question (at least in the naive
sense of comparing the energies of different states or their relative stability). Other
issues, perhaps cosmological, must come into play. We will save speculations on
these questions for later.
27.1 Non-renormalization theorems for world sheet perturbation theory

Let us turn, now, to compactified theories. Consider, first, a Type II theory compactified on a Calabi–Yau space. In this case, the low-energy theory has $N = 2$ supersymmetry. Again, this is enough to guarantee that there is no potential generated for the moduli, perturbatively or non-perturbatively. In other words, starting with a solution of the equations of the low-energy effective field theory, at lowest order in $g_s$ and $R^2/\alpha'$, we are guaranteed that we have an exact solution to all orders – and non-perturbatively – in both parameters.

Now consider the compactification of the heterotic string theory on the same Calabi–Yau space, with spin connection equal to the gauge connection. Then the world sheet theory, as we saw, has two left-moving and two right-moving supersymmetries. It is identical to the theory which describes the corresponding Type II background. But we just established that the Calabi–Yau space is a solution of the classical string equations, which means that there is a corresponding superconformal field theory with central charge $c = 9$. This is an exact statement; so the background corresponds to an exact solution of the classical string equations. This does not establish that the Calabi–Yau space corresponds to an exact vacuum quantum mechanically, as it does in the Type II case. For example, the intermediate states in quantum loops in the two theories are different.

We can establish this result in a different way. Consider the $h_{1,1}$ $(1, 1)$-forms, $b_{i\bar{J}}^{(a)}$; one of these is the Kahler form, where $b_{i\bar{J}} = g_{i\bar{J}}$. In world sheet perturbation theory we have seen that these fields decouple at zero momentum. The fact that all scattering amplitudes involving external $b$ particles vanish at zero momentum has consequences for the structure of the low-energy effective Lagrangian: only derivatives of $b$ appear in the Lagrangian. This is reminiscent of the couplings of Goldstone bosons; the Lagrangian, in world sheet perturbation theory, is symmetric under

$$b(x) \rightarrow b(x) + \alpha$$

(27.1)

for constant $\alpha$.

This result implies a non-renormalization theorem for $\sigma$-model perturbation theory; $b$ lies in a supermultiplet with $r^2$, the modulus which describes the size of the Calabi–Yau space. This is apparent from the fact that they are both Kaluza–Klein modes associated with the metric, $g_{i\bar{J}}$; $r^2$ is the symmetric part; $b$ is the antisymmetric part. So this is similar to the situation in which we could prove non-renormalization theorems in field theory. Different orders of $\sigma$-model perturbation theory are associated with different powers of $r^{-2}$. But in holomorphic quantities such as the superpotential and gauge coupling function, additional powers of $r^{-2}$ are accompanied by powers of $b$. So only terms which are independent of $r^{-2}$ are
permitted by the shift symmetry. As a result, the superpotential computed at lowest order is not corrected in \(\sigma\)-model perturbation theory. This means that particles which are moduli at the leading order in \(\alpha'\) are moduli to all orders of \(\sigma\)-model perturbation theory.

This non-renormalization theorem does not quite establish that these are good solutions of the classical string theory; there is still the possibility that non-perturbative effects in the \(\sigma\)-model will give rise to potentials for the lowest-order moduli. Indeed, our argument for the vanishing of the \(b\) couplings is not complete. At zero momentum, the vertex operator for \(b\), \(V_b\), is topological; while it is the integral of a total divergence, it does not necessarily vanish. There generally exist classical Euclidean solutions of the two-dimensional field theory – instantons – for which the vertex operator is non-zero. These world sheet instantons raise the possibility that non-perturbative effects on the world sheet will lift some or all of the vacuum degeneracy. For the \((2, 2)\) theories, however, we already know that this does not occur. We earlier argued, by considering the compactification of the related Type II theories, that these corresponding sigma models are exactly conformally invariant. It is possible (and not terribly difficult) by examining the structure of the two-dimensional instanton calculation ("world-sheet instanton") to show that no superpotential is generated. While we will not review this analysis here, the techniques involved are familiar from our discussion of four-dimensional instantons. One wants to determine whether instantons can generate a superpotential. One needs, as in four dimensions, to count fermion zero modes, and see if they can lead to a non-vanishing correlation function at zero momentum for an appropriate set of fields. In the \((2, 2)\) case, one finds that they cannot. One can then ask whether quantum corrections (small fluctuations) to the instanton result can yield such a correction. Here, one notes that, as in perturbation theory, holomorphy fixes uniquely the dependence on the coupling. So if the lowest-order contribution vanishes, higher orders vanish as well.

In the case of \((2, 0)\) compactifications of the heterotic string, the situation is more complicated. Perturbatively, we can argue, as before, that solutions of the string equations at lowest order are solutions to all orders in the \(\alpha'\) expansion. Non-perturbatively, however, the situation is less clear. For such compactifications, there is no corresponding Type II compactification, so we can not rely on the magic of \(N = 2\) supersymmetry. It is necessary to examine in detail the effects of world sheet instantons. In general, if one does the sort of zero-mode counting described above, one finds that it is possible to generate a superpotential. But in many cases, one can argue that there are cancellations, and the superpotential vanishes.

It is important to understand that the non-renormalization theorems do not imply that the Calabi–Yau manifold is itself an exact solution to the classical string equations; rather, the point is that there is guaranteed to exist a solution nearby. There
27.1 Non-renormalization theorems

...tadpoles for massive particles in \( \sigma \)-model perturbation theory. A tadpole corresponds to a correction of the equations of motion:

\[ \nabla^2 h + m^2 h = \Gamma. \]  

(27.2)

This is solved by a perturbatively small shift in the \( h \) field:

\[ h = -\frac{\Gamma}{m^2}. \]  

(27.3)

For the massless fields, however, one cannot find a solution in this way, and in general, if there is a tadpole, there is no nearby (static) solution of the equations. This is why the low-energy effective action is such a useful tool in addressing such questions: it is precisely the tadpoles for the massless fields which are important.

### 27.1.2 Non-renormalization theorems for string perturbation theory

In field theory, we proved non-renormalization theorems by treating couplings as background chiral fields, and exploring the consequences of holomorphy of the effective action as functions of these fields. In string theory, we have no coupling constants, but the moduli determine the effective couplings, and since they are themselves fields, they are restricted by the symmetries of the theory. We exploited this connection in the previous section to prove non-renormalization theorems for \( \sigma \)-model perturbation theory. In this section, we prove similar statements for string perturbation theory.

We begin with the heterotic string theory, on a Calabi–Yau manifold or an orbifold. In this case, we saw that there is a field, \( S \), which we called the dilaton (it is sometimes called the four-dimensional dilaton). The vertex operator for the imaginary part of this field, \( a(x) \), at \( k = 0 \), is simply:

\[ V_a = \int d^2 \sigma \epsilon^{ab} \partial_a X^\mu \partial_b X^\nu b_{\mu\nu}. \]  

(27.4)

This is, again, a total derivative on the world sheet. So this particle, which we saw earlier is an axion, decouples at zero momentum. So again there is a shift symmetry – this is just the axion shift symmetry. Again, this means that the superpotential must be independent of \( S \). But since powers of perturbation theory come with powers of \( S \), this establishes that the superpotential is not renormalized to all orders of perturbation theory!

As in the world sheet case, there can be non-perturbative corrections to the superpotential, and this raises the possibility that potentials will be generated for the moduli. We will see shortly that gluino condensation, as in supersymmetric field theories, is one such effect.
First, we consider other string theories. In the case of Type II compactified on a Calabi–Yau space, the $N = 2$ supersymmetry is enough to insure that no superpotential is generated perturbatively or non-perturbatively: Calabi–Yau spaces correspond to exact ground states of the theory, and the degeneracies are exact as well. As in field theories with $N = 2$ supersymmetry, corrections to the metric (Kahler potential) are possible. Theories with more supersymmetry (heterotic on tori or Type II theories on $K3$ spaces with $N = 4$ supersymmetry, or Type II on tori with eight supersymmetries) are even more restricted.

### 27.2 Fayet–Iliopoulos $D$-terms

In deriving the non-renormalization theorems for string perturbation theory, we established that there is no renormalization of the superpotential, or of the gauge coupling function beyond one loop. But this is not quite enough to establish that there is no renormalization of the potential. We must also check whether Fayet–Iliopoulos terms are generated. From field-theoretic reasoning, we might guess that any renormalization would occur only at one loop. In globally supersymmetric theories in superspace, a Fayet–Iliopoulos term has the form:

$$\zeta^2 D = \int d^4 \theta V.$$  \hspace{1cm} (27.5)

This term is just barely gauge invariant; under $V \rightarrow V + \Lambda + \Lambda^\dagger$, this is invariant because $\int d^4 \theta \Lambda = 0$ since $\Lambda$ is chiral. If we treat the gauge coupling (or any other couplings) as background fields, any would-be corrections to $D$ would have the form:

$$\int d^4 \theta g(S, S^\dagger)V$$  \hspace{1cm} (27.6)

which is only invariant if $g$ is a constant. Thus any $D$-term is independent of the coupling, in the normalization where $1/g^2$ appears in front of the gauge terms. So at most there is a one-loop correction.

Before going on to string theory, it is interesting to look at the structure of any one-loop term. Call the associated $U(1)$ generator $Y$. If supersymmetry is unbroken, massive fields come in pairs with opposite values of $Y$, so only massless fields contribute. The Feynman diagram which contributes to the $D$-term is shown in Fig. 27.1. It is given by:

$$\zeta^2 = \text{Tr}(Y) \int \frac{d^4 k}{(2\pi)^4} \frac{1}{k^2}.$$  \hspace{1cm} (27.7)

So a vanishing $D$-term requires that the trace of the $U(1)$ generator vanish. The one-loop diagram is quadratically divergent, but let’s rewrite this in a way which
27.2 Fayet–Iliopoulos $D$-terms

Fig. 27.1. The Feynmann diagram which contributes to the $D$-term.

resembles expressions we have seen in string theory. We can introduce a “Schwinger parameter,” which we will call $\tau_2$. Then:

$$\zeta^2 = 2\pi \text{Tr}(Y) \int_{0}^{\infty} d\tau_1 \int \frac{d^4k}{(2\pi)^4} e^{-2\pi\tau_2 k^2}$$ (27.8)

$$= \frac{1}{32\pi^3} \text{Tr}(Y) \int_{0}^{\infty} d\tau_2 \frac{1}{\tau^2_2} \int_{-1/2}^{1/2} d\tau_1.$$ (27.9)

We have written things in this way because we want to think of this as an integral over the modular parameter of the torus. At this stage, the integral is still quadratically divergent. But, under modular transformations, the complex $\tau$ plane is mapped into itself several times. We can define a fundamental domain,

$$\frac{1}{2} \leq \tau_1 \leq \frac{1}{2}, \quad |\tau| \geq 1.$$ (27.9)

If we restrict the integration to the fundamental domain, the result is finite. In string theories, this turns out to be the correct answer:

$$\zeta^2 = \frac{1}{192\pi^2} \text{Tr} Y.$$ (27.10)

This result can be derived by a straightforward string computation. But instead, in string models where $\text{Tr}(Y)$ is non-zero, we can give a low-energy field theory argument which completely fixes the coefficient of the $D$-term, and also sheds light on possible perturbative corrections. If $\text{Tr}(Y) \neq 0$, the low-energy theory has a gravitational anomaly. This anomaly is rather similar to the gauge anomalies we have discussed in field theory. It arises from a diagram with one external gauge boson and an external graviton. String models with such anomalies typically have gauge anomalies as well, which we can readily evaluate. As an example, consider the compactification of the $O(32)$ heterotic string on a Calabi–Yau space, with spin connection equal to the gauge connection. In this case, the low-energy gauge group is $SO(26) \times U(1)$. There are $h_{1,1}$ 26s with $U(1)$ charge 1, and $h_{2,1}$ 26s with $U(1)$ charge $-1$. There are also corresponding singlets, with charge +2 and $-2$ respectively. These are in precise correspondence with the fields we found in $E_6$; the 26s arise in parallel to the $O(10)$ 10s; the singlets to the $O(10)$ singlets. But
now it is clear that there are anomalies in the gauge symmetries. For example, there is a \( U(1) \times O(26)^2 \) anomaly proportional to

\[
A = (h_{2,1} - h_{1,1})
\]  

(27.11)

and a \( U(1)^3 \) anomaly:

\[
A' = (h_{2,1} - h_{1,1})(26 - 8).
\]  

(27.12)

On the other hand, this is a modular invariant configuration of string theory, so there should not be any inconsistency, at least in perturbation theory. So something must cancel the anomaly. The cancellation is actually a variant of the mechanism discussed originally by Green and Schwarz in ten dimensions, now specialized to four dimensions. We know that there is a coupling:

\[
\int d^2 \theta SW^2. 
\]  

(27.13)

This gives rise to a coupling of the axion to the \( \tilde{F}F \) terms of each group. The anomaly calculation in the low-energy theory implies a variation of the action proportional to the anomaly coefficient and \( \tilde{F}F \). So if the axion transforms under the gauge symmetry as

\[
a(x) \rightarrow a(x) + c \omega(x)
\]  

(27.14)

this can cancel the anomaly. It is crucial that the anomaly coefficients are the same for each group.

We can check whether this hypothesis is correct. If \( a(x) \) transforms, then it must couple to the gauge field. The required covariant derivative is

\[
D_\mu a = \partial_\mu a - \frac{1}{c} A_\mu.
\]  

(27.15)

So from the kinetic term in the action, there is a coupling of \( A_\mu \) to \( a \). One can compute this coupling without great difficulty and verify that it has the required magnitude.

More interesting, however, is to consider the implications of supersymmetry. We can generalize the coupling above to superspace. The transformation law for \( a \) now becomes a transformation law for \( S \):

\[
S \rightarrow S + \Lambda + \Lambda^\dagger
\]  

(27.16)

where \( \Lambda \) is the chiral gauge transformation parameter. The gauge-invariant action for \( S \) is:

\[
- \int d^4 \theta \ln \left( S + S^\dagger - \frac{1}{c} V \right).
\]  

(27.17)
If we Taylor series expand this Lagrangian, we see that, in addition to the $A_\mu \partial^\mu a$ coupling, we generate a Fayet–Iliopoulos $D$-term:

$$\int d^4\theta \frac{1}{c(S + S^\dagger)} V. \tag{27.18}$$

One can verify that this term – and the other terms implied by this analysis – are present. First, we can ask: at what order in perturbation theory should each of these terms appear? To establish this, we need to remember that the standard supergravity Lagrangian is written in a frame where $M_p^2$ appears in front of the Einstein term in the effective action. In the string frame, it is the dilaton – essentially $S$ – which appears out front. If we rescale the four-dimensional metric by:

$$g_{\mu\nu} \to S g_{\mu\nu} \tag{27.19}$$

then $S$ appears in front of the Lagrangian. With this same rescaling, the “kinetic” term, which had an $S$ out front, has $S^3$. The Fayet–Iliopoulos $D$-term, originally has a $1/S$ out front. Correspondingly, the resulting scalar mass term would be proportional to $1/S^2$. After the metric rescaling, this is independent of $S$, i.e. in the heterotic string theory, the $D$-term should appear at one loop, in accord with our field theory intuition. Similarly, the coupling $A_\mu \partial^\mu a$ should appear at one loop, while there should be a contribution to the cosmological constant at two loops. All of these can be found by straightforward string computations (some of these are described in the Suggested reading).

In essentially all known examples, this one-loop $D$-term does not lead to supersymmetry breaking. There always seem to be fields which can cancel the $D$-term. Consider, again, the $O(32)$ theory. Here we can try to cancel the $D$-term by giving an expectation value to one of the singlets, $1_{-2}$. The question is whether this gives a non-zero contribution to the potential when we consider the superpotential. The most dangerous coupling is a term $1_{-2}1_{+2}$ involving some other singlet. But such terms are absent at lowest order, and their absence to higher orders is guaranteed by the non-renormalization theorems. Charge conservation forbids terms of the form $1^n_{-2}$; there are no other dangerous terms. So this corresponds to an exact “F-flat” direction of the theory. So in perturbation theory there exists a good vacuum. While a general argument is not known, empirically this possibility for cancellation appears to arise in every known example.

What does the theory look like in this new vacuum?

1. Supersymmetry is restored and the vacuum energy vanishes.
2. The $U(1)$ gauge boson has a mass-squared of order $g_s^2$ times the string scale.
3. The longitudinal mode of the gauge boson is principally the imaginary part of the charged scalar field whose vev canceled the $D$-term. There is still a light axion.
From the perspective of a very-low-energy observer, the $D$-term is not a dramatic development. It plays some role in determining physics at a very-high-energy scale (albeit not quite as high as the string scale). What is perhaps most impressive is the utility of effective field theory arguments in sorting out a microscopic string problem. Prior to the discovery of the $D$-term, for example, there had been many papers “proving” a strict non-renormalization theorem for the potential; this, we see, is not correct (it is not hard to determine, in retrospect, what went wrong in the original proofs). The effective field theory arguments make clear when the potential is renormalized in perturbation theory and when it is not. They also permit easily finding the “new vacuum” in cases where a Fayet–Iliopoulos term appears. It is possible, in principle, to find this vacuum by stringy methods, but this is distinctly more difficult. Finally, these arguments give insight into the non-perturbative fate of the non-renormalization theorems.

### 27.3 Gaugino condensation

We have seen that in string theory, if supersymmetry is unbroken at tree level, it is unbroken to all orders of perturbation theory. The argument, as in field theory, allows exponential dependence on the coupling. In the case of the heterotic string compactified on a Calabi–Yau space, gaugino condensation, as in supersymmetric field theories, generates a superpotential on the moduli space.

Consider the $E_8 \times E_8$ theory compactified on a Calabi–Yau space, with spin connection equal to the gauge potential, and without Wilson lines. In this case, there is an $E_6 \times E_8$ gauge symmetry. There are typically several fields in the 27 of $E_6$, but there are no chiral fields transforming in the $E_8$. So one has a pure $E_8$ supersymmetric gauge theory. The couplings of the $E_6$ and $E_8$ are equal at the high scale, so the $E_8$ coupling becomes strong first. This leads, as we have seen, to gaugino condensation. We have also seen that at tree level there is a coupling:

$$ SW_\alpha^2. $$  \hfill (27.20)

Just as before, this leads to a superpotential for $S$:

$$ W(S) = Ae^{-3S/b_0}. $$  \hfill (27.21)

One often hears this described as a “field theory analysis,” as if it is not necessarily a feature of the string theory. But string theory obeys all of the principles of quantum field theory. If we correctly integrate out high-energy string effects, the low-energy analysis is necessarily reliable. So the only question is: are there terms in the low-energy effective action that lead to larger effects. One might worry that, since we understand so little about non-perturbative string theory, it would be hard to address
27.4 Obstacles to a weakly coupled string phenomenology

We have seen that string theory is a theory without dimensionless parameters. This is an exciting prospect, but it also raises the question: how are the parameters of low-energy physics determined? We have argued that the answer to this question lies in the dynamics of the moduli: the expectation values of these fields determine the couplings in the low-energy Lagrangian.

In non-supersymmetric string configurations, perturbative effects already lift the degeneracy among different vacua, giving rise to a potential for the moduli. In the previous section, we have learned that in supersymmetric compactifications non-perturbative effects generically lift the flat directions of the potential. In other words, the moduli are not truly moduli at the quantum level. At best, we can speak of approximate moduli in regions of the field space where the couplings are weak. The potentials, both perturbative and non-perturbative, all tend to zero at zero coupling. This is not surprising; with a little thought, it becomes clear that this behavior is not specific to perturbation theory or some particular non-perturbative phenomenon such as gaugino condensation. At very weak coupling, we expect that the potential always tends rapidly to zero. This means that if the potential has a minimum, this
occurs when the coupling is not small. This is troubling, for it means that it is likely to be hard – if possible at all – to do computations which will reveal detailed features of the state of string theory (if any) which describes the world we see around us.

In the next chapter, we will see that much is known about non-perturbative string physics. Most striking are a set of dualities, which relate regimes of very strong coupling in one string theory to weak coupling in another. While impressive, these, by themselves, do not help with the strong coupling problem we have elucidated above. If, at very strong coupling, the theory is equivalent to a weakly coupled theory, the potential will again tend to zero. In other words, it is likely that stable ground states of string theory exist only in regions where no approximation scheme is available.

Perhaps just as troubling is the problem of the cosmological constant. Neither perturbative nor non-perturbative string theory seems to have much to say. The potentials are more or less of the size one would guess from dimensional analysis (and the expected dependence on the coupling). Perhaps most importantly, they are, up to powers of coupling, as large as the scale set by supersymmetry breaking.

There are, however, some reasons for optimism. Perhaps the most important is provided by nature itself: the gauge and Yukawa couplings of the Standard Model are small. Another is provided by string theory. As we will discuss later, there are ways in which large pure numbers can arise. These might provide mechanisms to understand the smallness of couplings, even in situations where asymptotically the potential vanishes. Finally, we will see that there is, at present, only one proposal to understand the smallness of the cosmological constant, and string theory may provide a realization of this suggestion.

**Suggested reading**

The result that there are no continuous global symmetries in string theory is a fundamental one. For the heterotic theory, it appears in Banks and Dixon (1988). Non-renormalization theorems for world sheet perturbation theory and issues in construction of (0, 2) models are described by Witten (1986) and by Green et al. (1987). The non-renormalization theorem for string perturbation theory is described by Dine and Seiberg (1986). The space-time argument for the Fayet–Iliopoulos $D$-term appears in Dine et al. (1987c); world sheet computations appear in Atick et al. (1987) and Dine et al. (1987a). World sheet instantons are discussed in Dine et al. (1986, 1987b); cancellations of instanton effects relevant to (0, 2) theories are studied by Silverstein and Witten (1995).
In the previous chapter, we were forced to face the fact that string theory, if it describes nature, is not weakly coupled. On the other hand, the very formulation we have put forward of the theory is perturbative. We have described the quantum mechanics of single strings, and given a prescription for calculating their interactions order by order in perturbation theory in a parameter $g_s$. There is a parallel here to Feynman’s early work on relativistic quantum theory: Feynman guessed a set of rules for computing perturbative amplitudes of electrons. In this case, however, one already had a candidate for an underlying description: quantum electrodynamics. It was Dyson who clarified the connection. For Abelian theories, the non-perturbative theory probably does not really exist, but in the case of non-Abelian gauge theories it does. The field theoretic formulation provides an understanding of the underlying symmetry principles, and access to a trove of theoretical information.

A string field theory would be a complicated object. The string fields themselves would be functionals of the classical two-dimensional fields which describe the string. The quantization of such fields is sometimes called “third quantization.” Much effort has been devoted to writing down such a field theory. For open strings, one can write relatively manageable expressions which reproduce string perturbation theory. For closed strings, infinite sets of contact interactions are required. But apart from their cumbersome structure, there are reasons to suspect that this is not a useful formulation. There would seem to be, for example, vastly too many degrees of freedom. At one loop, we have seen that string amplitudes are to be integrated only over the fundamental region of the moduli space. Naively a field theory which simply describes all of the states of the string would have amplitudes integrated over the whole region, and the cosmological constant would be extremely divergent. The contact terms mentioned above solve this problem, but not in a very satisfying way.

Despite this, there has been great progress in understanding non-perturbative aspects of the known string theories. Most strikingly, it is now known that all theories
Beyond weak coupling: non-perturbative string theory

with 16 or more supersymmetries are the same. Many tools have been developed
to study phenomena beyond string perturbation theory, especially \( D \)-branes and
supersymmetry. There exist some cases where non-perturbative formulations of
string theory are possible, and we will discuss them briefly in this chapter. They
are technically and conceptually much simpler than string field theory. They have
a puzzling, perhaps disturbing feature, however: they are special to strings prop-
agating in particular backgrounds. It is as if, in Einstein’s theory, for each pos-
sible geometry, one had to give a different Hamiltonian. All of these results are
“empirical.” They have been developed by collecting circumstantial evidence on a
case-by-case basis. There is still much which is not understood. In the last chapter,
we will discuss how this developing understanding might lead to a closer connection
of string theory to nature.

28.1 Perturbative dualities

Before considering examples of weak–strong coupling dualities, we return to the
large/small radius duality we studied in Section 25.3. Many of the dualities we will
study have a similar flavor, even though they cannot be demonstrated so directly.
We saw that there is an equivalence of the heterotic string theory at small radius
to the theory at large radius. By examining the action of these transformations at
their fixed points, we saw that these duality symmetries are gauge symmetries. We
could ask, as well, the significance of duality transformations in the IIA and IIB
theories. As in other closed strings, in addition to transforming the radii, the duality
transformation takes:

\[
\begin{align*}
\partial X^9 &\rightarrow -\partial X^9; \\
\bar{\partial} X^9 &\rightarrow \bar{\partial} X^9.
\end{align*}
\]  

(28.1)

Because of world sheet supersymmetry, it has the same action on the fermions;
\( \psi^9 \rightarrow -\psi^9; \bar{\psi}^9 \rightarrow \bar{\psi}^9 \). But under this the chirality operator appearing in the GSO
projector is reversed in sign, i.e. duality interchanges the IIA and IIB theories; \( \text{the small-radius IIA theory is equivalent to the large-radius IIB theory} \), and vice versa.

There are other perturbative connections. For example, the compactified \( O(32) \)
heterotic string theory is equivalent to the \( E_8 \times E_8 \) theory.

28.2 Strings at strong coupling: duality

Duality is a term used in physics to label different descriptions of the same physical
situation. At the level of perturbation theory, we have learned about five apparently
different string theories. Based on the perturbative dualities discussed above, we
see that there are at most three inequivalent string theories, the Type I, Type II, and
heterotic theories. But it is tempting to ask whether there are more connections. In
this chapter, we will see that all of the known string theories are equivalent in a similar way, but these equivalences relate small and large coupling. For example, the strong coupling limit of the $O(32)$ heterotic string theory is the weak coupling limit of Type I string theory; the strongly coupled limit of $E_8 \times E_8$, compactified to six dimensions on a torus, is the weakly coupled limit of Type II theory compactified on a K3 manifold (K3 manifolds are essentially four-dimensional Calabi–Yau spaces); the ten-dimensional Type II theory is self-dual, and, perhaps most intriguingly of all, the strong coupling limit of Type IIA theory in ten dimensions is described, at low energies, by a theory whose low-energy limit is eleven-dimensional supergravity.

Lacking a non-perturbative formulation of the theory, the evidence for these connections is necessarily circumstantial. While circumstantial, however, it is compelling. All of the evidence relies on supersymmetry. We will not be able to review all of this here, but will try to give the flavor of some of the arguments. Supersymmetry, especially supersymmetry with 16 or 32 supercharges, allows one to write a variety of exact formulas, for Lagrangians (based on strong non-renormalization theorems) and for spectra (based on BPS formulas) which can be trusted in both weak and strong coupling limits. This allows detailed tests of the various dualities.

### 28.3 D-branes

When we discussed strong–weak (electric–magnetic) dualities in field theory, topological objects played a crucial role. The same is true in string theory, where the solitons are various types of branes. In general, a $p$-brane is a soliton with a $p + 1$-dimensional world volume, so a 0-brane is a particle, a 1-brane a string, a 2-brane a membrane, and so on. In general, one might construct these by solving complicated non-linear differential equations. But a large and important class of topological objects can be uncovered in string theory in a different – and much simpler – way. These are the $D$-branes. These branes fill an important gap in our understanding of the Type I and Type II theories. In these theories, we encountered gauge fields in the Ramond–Ramond sectors: two-forms in Type I, one-forms and three-forms in the IIA theories, zero-forms, two-forms, and four-forms in the IIB. One natural question is: where are the charged objects that couple to these fields? They are not within the perturbative string spectrum. The vertex operators for these fields involved the gauge-invariant field strengths only, so in perturbation theory there are no objects with minimal coupling. The answer is the $D$-branes. Their masses (tensions) are proportional to $1/g_s$, so at weak coupling they are very heavy. This is why they are not encountered in the string perturbation expansion.

When we discussed open strings, we noted that there are two possible choices of boundary conditions: Neumann and Dirichlet. At first sight, Neumann boundary
conditions appear more sensible; Dirichlet boundary conditions would violate translational invariance, implying that strings end at a particular point(s). But we have already encountered violations of translational invariance within translationally invariant theories: solitons, such as magnetic monopoles or higher-dimensional objects like cosmic strings and domain walls. Admitting the possibility of Dirichlet boundary conditions for some or all of the coordinates leads to a class of topological objects known as D-branes (for Dirichlet branes). If \( d - p - 1 \) of the boundary conditions are Dirichlet, while \( p + 1 \) are Neumann, the system is said to describe a \( Dp \)-brane.

We can be quite explicit. Start first with the bosonic string. For the Neumann directions, we have our previous open string mode expansion of Eq. (21.16). For the Dirichlet directions, we have:

\[
X^I = x_0^I + i \sum_{n \neq 0} \frac{1}{n} \alpha_n^I e^{-in\tau} \sin(n\sigma) \quad I = 1, d - p - 1.
\]  

(28.2)

Note that there are no momenta associated with the Dirichlet directions. The \( x_0^I \)s should be thought of as collective coordinates. We will argue shortly that the tension of the branes is proportional to \( M^{p+1}_5 / g_s \).

Consider an “extreme” case, that of a \( D0 \)-brane. There are 25 collective coordinates and no momenta, so this object is a conventional soliton. In field theory, the excitations near the soliton, which describe scattering of mesons (field theory excitations) from the soliton must be found by studying the eigenfunctions of the quadratic fluctuation operator. But here they are very simple: they are just the excitations of the open string. As a second example, consider a \( D3 \)-brane. Now the momentum has four components. So the excitations which propagate on the brane are four-dimensional fields. These break up into two types. The Neumann fields, \( X^\mu \), give rise to a massless gauge boson, the state \( \alpha^\mu_{-1}|0\rangle \); the Dirichlet fields, \( X^I \), give rise to massless scalars on the brane \( \alpha^I_{-1}|0\rangle \). In the superstring version of this construction, there are six scalars and a gauge boson, and their superpartners. In \( N = 1 \) language, this is a vector multiplet and three chiral multiplets, the content of \( N = 4 \) Yang–Mills theory with gauge group \( U(1) \).

Before considering some of these statements in greater detail, let us explore a further aspect of this construction. Suppose we have several branes, say \( D3 \)-branes, parallel to each other. Here parallel just means that the strings which end on these branes have Dirichlet or Neumann boundary conditions in the same direction. Now, however, we have the possibility that the strings end on different branes. Take the simplest case of two branes. If the branes are separated by a distance \( r \), in addition to the modes above, labeled by the collective coordinate \( x^I_i \), \( i = 1, 2 \), we have to
allow for expansions of the form:

\[ X^I(\sigma, \tau) = x^I_i + \sigma \frac{r}{\pi} (x^I_j - x^I_i) + i \sum_{n \neq 0} \frac{1}{n} \alpha^I_n e^{-in\tau} \sin(n\sigma) \quad I = 1, \ldots, d-p-1. \]  

(28.3)

There are two such configurations, one starting on the first brane and ending on the second, and one starting on the second and ending on the first. The ground states in these sectors have mass-squared proportional to \( r^2 \). For \( r \neq 0 \), all of these states are massive. The massless bosons consist of a \( U(1) \) gauge boson on each brane, as well as scalars. As \( r \to 0 \), we have two additional massless gauge bosons. If we generalize to \( n \) branes, we have \( n \) massless gauge bosons and \( 6n \) scalars; as we bring the branes close together, we have \( n^2 \) gauge bosons and \( 6n^2 \) scalars.

There is a natural conjecture as to what is going on here. When all of the branes are on top of one another, we have a \( U(n) \) gauge symmetry, with \( 3n \) complex scalars transforming in the adjoint representation of the group. As the branes are separated, the adjoint scalars acquire (commuting) expectation values; these break the gauge symmetry to \( U(1)^n \), giving mass to the other gauge bosons. In principle, we would like to check that these \( n^2 \) gauge bosons interact as required for Yang–Mills theories, as we did for the gauge bosons of the heterotic string. This is more challenging here, since we need vertex operators which connect strings ending on different branes and we will not attempt this. We will provide further evidence for the correctness of this picture shortly.

The branes break some of the supersymmetry of the Type II theory in infinite space; instead of 32 conserved supercharges, there are 16. A simple way to understand this uses the light cone gauge construction. There are now open strings ending on the brane. For the world sheet fermions, the boundary conditions relate the left and right movers on the string. Calling these \( S_a \) and \( \tilde{S}_a \), we have

\[ S_a(\sigma, \tau) = \sum_n S^n_a e^{-in(\tau + \sigma)} \quad \tilde{S}^a(\sigma, \tau) = \sum_n \tilde{S}^n_a e^{-in(\tau - \sigma)}. \]  

(28.4)

Recall that half of the supercharges have the very simple form:

\[ Q^a = \int d\sigma S^a \quad \tilde{Q}^a = \int d\sigma \tilde{S}^a \]  

(28.5)

so \( Q^a = \tilde{Q}^a \). This is the structure of a broken supersymmetry generator, with \( S \) the goldstino. The same is true for the other set of supercharges. Other configurations of branes, such as non-parallel sets of branes, preserve less supersymmetry. Brane–anti-brane configurations preserve no supersymmetry at all.

We can imagine other sets of branes, which would respect different amounts of supersymmetry. If we have branes which are not parallel, for example, different sets
of supersymmetries will be preserved. In order to count supersymmetries, we need
to compare the supersymmetries on different branes, at different angles relative to
one another.

28.3.1 Brane charges

We have seen that the simplest $D$-brane configurations preserve half of the super-
symmetries. In other words, they are BPS states. Typically BPS states are associated
with conserved charges. In the case of IIA and the IIB theories, in the Ramond–
Ramond sectors there are gauge fields, but, in perturbation theory, no charged
objects. Polchinski guessed – and showed – that the objects which carry Ramond–
Ramond charges are $D$-branes. In the IIA case, the gauge fields are a one form and a
three form; in the IIB case they are a zero-form, a two-form, and a (self-dual) four-
form. In relativistic mechanics, a gauge field couples to a particle – a zero-brane.
We have seen that a two-index tensor couples naturally to a string – a one-brane.
So this suggests that in the IIA theory, there should be $D_p$-branes with $p$ even, cou-
pling to the corresponding R–R gauge fields, while in the IIB theory there should be
$D_p$-branes with $p$ odd. Polchinski verified this by direct calculation. He computed
the one-loop amplitude for two separated branes. For large separations, he found
the poles associated with exchange of the massless gauge fields (more precisely,
for fixed separation, $r$, one should see falloff with powers of $1/r$). His calculation
not only yields the brane charges, but it also gives the brane tensions.

Consider the case of two branes, separated by a distance $y$. In empty flat space,
the trace over states in the one-loop amplitude for open strings gives a result of the form:

$$\mathcal{A} = C \int_0^\infty \frac{dt}{t^2}. \quad (28.6)$$

The power of $t$ arises from the momentum integral, $\int d^8 k \exp(-k^2)$, as well as
from the manipulation of the oscillator traces. The main difference in the case of
two separated branes is that the mass-squared has a contribution from the brane
separation, $y^2$, and $9 - p$ coordinates of the brane are fixed, so they don’t have
associated momenta. So the result has the form:

$$\mathcal{A} = C \int_0^\infty \frac{dt}{t^2} (8\pi^2 \alpha'^2)\frac{(9-p)/2}{2\pi \alpha'} \exp\left(-\frac{ty^2}{2\pi \alpha'}\right) \sim y^{-(9-p)} \sim G_{9-p}(y). \quad (28.7)$$

Here $G_d(y)$ is the scalar Green function in $d$ dimensions. So one can think of a
potential between the branes associated with the exchange of massless states. These
massless states are antisymmetric tensor fields and their superpartners, as well as
gravitons and gravitinos. These contributions can be isolated, and the tensions and
28.4 Branes from T-duality of Type I strings

Charges of the $D$-branes determined. In the case of the superstring, the full potential vanishes due to boson and fermion cancellations.

28.3.2 Brane actions

We are familiar with the actions for zero-branes and one-branes. The action for a general $p$-brane is a generalization of these:

$$S_p = -T_p \xi \int d^{p+1} \xi \det \left( \frac{\partial X^\mu}{\partial \xi^a} \frac{\partial X^v}{\partial \xi^b} \eta_{\mu \nu} \right)^{1/2}. \quad (28.8)$$

In the zero-brane case, this is the action for a particle; $X^\mu(\tau)$ is the collective coordinate which describes the position of the soliton, and $T_0$ is its mass. For a general background with a bulk metric, dilaton and antisymmetric tensor field this generalizes to

$$S_p = -T_p \int d^{p+1} \xi e^{-\Phi} \left[ - \det(G_{ab} + B_{ab} + 2\pi \alpha' F_{ab}) \right]^{1/2}. \quad (28.9)$$

The terms involving the metric and antisymmetric tensor are similar to those we have encountered elsewhere in string theory, and their form is not surprising. The $e^{-\Phi}$ reflects the fact that in the open string sector, the coupling constant is the square root of that of the closed string sector.

28.4 Branes from T-duality of Type I strings

There is another way to think about $D$-branes, which provides further insight. We have seen that closed string theories exhibit a duality between large and small radius. In the heterotic theory there is an exact equivalence of the theories at large and small radius, which can be understood as a gauge symmetry. In Type II theories, $T$-duality relates two apparently different theories. It is natural to ask what is the connection between large and small radius in theories with open strings. Open strings have momentum states, but no winding states. So there cannot be a self-duality. Instead, we look for an equivalence between the open string theory at one radius and some other theory at the inverse radius. Here we uncover $D$-branes.

Consider the boundary conditions on the strings in the compactified direction. For the closed string fields, the effect of the duality transformation is to take:

$$X_L \rightarrow X_L \quad X_R \rightarrow -X_R. \quad (28.10)$$

In terms of left- and right-moving bosons in open string theories, Neumann boundary conditions are the conditions

$$\partial_\tau X = (\partial_{\sigma_+} + \partial_{\sigma_-})X = 0. \quad (28.11)$$
Beyond weak coupling: non-perturbative string theory

So after a $T$-duality transformation, we would expect

$$(\partial_{\sigma_+} - \partial_{\sigma_-})X = \partial_\sigma X = 0,$$  \hfill (28.12)

i.e. we have traded Neumann for Dirichlet boundary conditions. While this follows from simple calculus manipulations, it is instructive to formulate this in terms of the mode expansion for the open string. Ordinarily, we have:

$$X^9 = x^9_i + \frac{1}{2}p(\tau + \sigma) + \frac{1}{2}p(\tau - \sigma) + i \sum_{n\neq 0} \frac{1}{n} \left( \alpha^9_n e^{-in(\tau+\sigma)} + \alpha^9_n e^{-in(\tau-\sigma)} \right).$$  \hfill (28.13)

The effect of the duality transformation is to change the sign of the terms which depend on $\tau - \sigma$. So instead of writing an expansion in terms of cosines, we have an expansion in terms of sines:

$$X^9 = x^9_0 + p\sigma + i \sum_{n\neq 0} \frac{1}{n} \alpha^9_n e^{-in\tau} \sin(n\sigma).$$  \hfill (28.14)

These are precisely the Dirichlet branes. Note the role of $p$: in the $T$-dual picture, it is a sort of winding: it describes strings which start on the brane, wind around the compact dimension some number of times, and then end on the brane.

This $T$-duality of open strings also allows us to better understand the appearance of gauge interactions associated with stacks of branes. In the original open string picture, gauge degrees of freedom are described by Chan–Paton factors, i.e. charges on the ends of the string. In the case of Type I strings, these are described by states of the form $|AB\rangle$, $A, B = 1, \ldots, 32$. Now consider a $U(16)$ subgroup of $O(32)$. The string ends carry labels, $i, j$, within $U(16)$. Taking the diagonal generators of $U(N)$ to be the matrices

$$T_1 = \text{diag}(1, 0, 0, \ldots), \quad T_2 = \text{diag}(0, 1, 0, \ldots),$$  \hfill (28.15)

etc., the state $(\vec{i}, j)$ carries charge $-1$ under $T_i$, $+1$ under $T_j$, and zero under the other generators.

We can consider constant, background gauge fields in the 9 direction. We can write these as:

$$A = \text{diag}(a_1, a_2, \ldots, a_{16}).$$  \hfill (28.16)

This has a gauge-invariant description in terms of the Wilson line:

$$U = e^{i \oint d\vec{x} \cdot \vec{A}},$$  \hfill (28.17)

where the integral is taken in the periodic directions. Such a background gauge field breaks the gauge symmetry to $U(1)^{16}$, in general; the other gauge bosons should
gain mass. In field theory, the corresponding mass terms are proportional to

\[ [A\mu, A^9]^2 \]  

so the diagonal gauge bosons are massless, and those corresponding to the non-Hermitian generator

\[ T_{ij}^{kl} = \delta_i^k \delta_j^l \]  

have mass-squared

\[ m^2 = (a_i - a_j)^2. \]

This is similar to the calculations we did of symmetry breaking in grand unified theories.

We would like to understand how this result arises directly in the string theory. It is simplest to consider the case of a string which is constant in \( \sigma \). The coupling of the string depends on the Chan–Paton factors. In the light cone, the action in the presence of a gauge field is like that of a particle:

\[ \frac{1}{2} \int d\tau \left( \left( \frac{\partial X^9}{\partial \tau} \right)^2 + (a_i - a_j) \frac{\partial X^9}{\partial \tau} \right). \]

For a non-constant string, the situation is somewhat more complicated, since the gauge fields couple at the string end points.

The extra term modifies the canonical momenta. These are now:

\[ P = \frac{n}{R} = \frac{\partial X^9}{\partial \tau} + (a_i - a_j). \]

This means that the leading term in the string mode expansion is:

\[ X^9 = \left( \frac{n}{R} - (a_i - a_j) \right) \tau. \]

This gives an extra contribution to the mass. If \( n = 0 \), this is exactly what we expect from field-theoretic reasoning.

Now let’s consider the \( T \)-dual picture. Under \( T \)-duality, the zero-mode part of \( X \) transforms into:

\[ X^9 = x_0 + \left( \frac{n}{R} - (a_i - a_j) \right) \sigma. \]

For \( i = j \), this corresponds to a string beginning and ending on the same \( D \)-brane. For \( i \neq j \), the string ends at different points, i.e. on separated \( D \)-branes. At least for the Type I theory, we have derived the picture we conjectured earlier: a stack of \( N \) coincident branes describes a \( U(N) \) gauge symmetry; as the branes are separated, the gauge symmetry is broken by a field in the adjoint representation.
28.4.1 Orientifolds

We have seen that we can understand the appearance of $D$-branes by considering $T$-duality transformations of open strings. The Type I theory is a theory of oriented strings. In the closed string sector, the action has a parity symmetry, which interchanges left and right on the world sheet. Calling the corresponding operator $\Omega_1$, one keeps only states which are invariant under the action of $\Omega$. This is necessary for the consistency of interactions of open and closed strings. This means that closed string states like

$$\alpha_{-2}\bar{\alpha}_{-1}\bar{\alpha}_{-1}|0\rangle$$ (28.25)

are not allowed, but symmetrized combinations such as

$$\alpha_{-2}\bar{\alpha}_{-1}\bar{\alpha}_{-1} + \bar{\alpha}_{-2}\alpha_{-1}\alpha_{-1}|0\rangle$$ (28.26)

are permitted. This projection is similar to the orbifold projections we have encountered earlier.

Consider the action of $\Omega_1$ in the $T$-dual theory. We have seen that in terms of the original fields,

$$X^{9'} = -X^9_L + X^9_R.$$ (28.27)

So the effect of interchanging left and right is to change the sign of $X^9$, i.e. $\Omega_1$ is a combination of a world sheet parity transformation and a reflection in space-time.

The effect of this projection on states is similar to a $Z_2$ orbifold projection. We can combine momentum states to form states with definite transformation properties under the reflection:

$$|p\rangle \pm | -p\rangle.$$ (28.28)

Gravitons, for example, in the non-compact directions, $G_{\mu\nu}$, must have momentum states which are even; in coordinate space, this means that graviton states must be even functions of $x$. The fields $G_{\mu\nu}^{9}$ must be odd functions, and so on. It is as if there is an entity, the orientifold, sitting at the origin – the fixed point of the reflection. This object in fact has a negative tension. One way to see this is simply to note that the effect of the $T$-duality transformation was to produce a set of $D$-branes. These branes have a positive tension. From the point of view of the non-compact dimensions, this is a cosmological constant. But the original theory had no such cosmological constant – this must be canceled by the orientifold.

Just as it is not necessary to start from the Type I theory and its dualities to encounter $D$-branes, it is not necessary to start from the Type I theory to consider orientifolds. Starting from Type II theories, in particular, we can perform a projection by world sheet parity times some $Z_2$ space-time symmetry. For example,
consider a Type II theory with a single compact dimension. On this theory, we can make a projection which is a combination of world sheet parity, \( \Omega \), and reflection in the compact dimension.

28.5 Strong–weak coupling dualities: the equivalence of different string theories

We have seen that at weak coupling, there are a variety of connections between different string theories which are surprising from a field-theoretic perspective. The heterotic string, compactified on a circle of very large radius, is equivalent to a string theory compactified at very small radius (with a different coupling). The Type IIA theory at large radius is equivalent to the IIB theory at small radius. The \( O(32) \) heterotic string is equivalent to the \( E_8 \times E_8 \) theory. All of these equivalences involve significant rearrangement of the degrees of freedom. Typically Kaluza–Klein modes, which are readily understood from a space-time field theory point of view, must be exchanged with winding modes, which seem inherently “stringy.” So perhaps it is not surprising that there are other equivalences, involving weak and strong coupling. Again, we have had some inkling of this in field theory, when we studied \( N = 4 \) Yang–Mills theory. There, the theory at weak coupling is equivalent to a theory at strong coupling. To see this equivalence, one needs to significantly rearrange the degrees of freedom. States with different electric and magnetic charge exchange roles, as the coupling is changed from strong to weak.

In string theory, there is a complex web of dualities. The IIB theory in ten dimensions exhibits a strong–weak coupling duality very similar to that of \( N = 4 \) Yang–Mills theories; weak and strong coupling are completely equivalent. The \( O(32) \) heterotic string theory, in ten dimensions, is equivalent at strong coupling to the weakly coupled Type I theory. These relations are surprising, in that these theories appear to involve totally different degrees of freedom at weak coupling. But there are more surprises still. The strong coupling limit of the IIA theory in ten dimensions is a theory whose low-energy limit is eleven-dimensional supergravity. If we allow for compactifications of the theory, this set of dualities is already enough to establish an equivalence of all string theories, as well as some as yet not fully understood theory whose low-energy limit is eleven-dimensional supergravity. But as we compactify, we find further, intricate relations. For example, the Type IIA theory on \( K3 \) is equivalent to \( E_8 \times E_8 \) on \( T^4 \). Given that all of the sensible theories of quantum gravity we know are equivalent, it is plausible that, in some sense, there is a unique theory of quantum gravity. As we will see, however, we only know this reliably for theories with at least 16 supercharges. For theories with four or less, this situation is less clear; it is by no means obvious that the statement is even meaningful.
In the next sections, we will explore some of these dualities, and the evidence for them. We will also discuss two particularly surprising equivalences. We will argue that certain string theories are equivalent to quantum field theories – even to quantum mechanical systems. The very notion of space-time in this framework will be a derived concept.

### 28.6 Strong–weak coupling dualities: some evidence

In the case of $T$-dualities, those dualities which relate the behavior of string theories at weak coupling and different radii, it is straightforward to understand the precise mappings between the different descriptions. Lacking a general non-perturbative definition of string theory, it is not possible to do something similar in the case of strong–weak coupling dualities. Instead, one can try to put together compelling circumstantial evidence. Without supersymmetry, even this is essentially impossible. But in the presence of sufficient supersymmetry one has a high degree of control over the dynamics. Evidence for equivalence can be provided by studying the following.

1. The effective action: in ten or eleven dimensions, the terms in the action with up to two derivatives are uniquely determined by supersymmetry, so they are not corrected either perturbatively or non-perturbatively. A similar statement holds for $N \geq 4$ actions in four (and actions with varying degrees of supersymmetry in between). In some cases, one can check higher-derivative terms in the effective action as well.

2. The spectrum of BPS objects: in many cases, the low-lying states are BPS objects. They cannot disappear from the spectrum as the coupling or other parameters are varied. With 16 or more supercharges, they obey exact mass formulae. The identity of the BPS states for different theories provides non-trivial evidence for these equivalences.

We will explore only some of the simplest connections here, but it is important to stress that these identifications are often subtle and intricate. In many instances where one might have thought the dualities mentioned above might fail, they do not.

#### 28.6.1 IIA → eleven-dimensional supergravity (M theory)

We start with the IIA theory, where we can readily access both aspects of the duality. Comparing the actions of eleven-dimensional supergravity and the IIA theory is particularly straightforward, as the Lagrangian of the IIA theory is often obtained by compactifying eleven-dimensional supergravity on a circle, keeping only the zero modes. The basic degrees of freedom in eleven dimensions are the graviton, $g_{MN}$, the antisymmetric tensor gauge field, $C_{MNO}$, and the gravitino, $\psi_M$. 
We are not going to work out the detailed properties of this theory, but it is a useful exercise to check that the numbers of bosonic and fermionic degrees of freedom are the same. As usual, we can count degrees of freedom by going to the light cone (or using the “little group,” the group of rotations in \( D = 11 - 2 = 9 \)). The metric is a symmetric, traceless tensor; for the gravitino, we need also to impose the constraint \( \gamma^I \psi_i = 0 \). For the metric, then, we have \( (9 \times 10)/2 - 1 = 44 \), while from the three-index antisymmetric tensor we have \( (9 \times 8 \times 7)/3! = 84 \), for a total of 128 bosonic degrees of freedom. From the gravitino, we have \( 9 \times 16 - 16 = 128 \) degrees of freedom.

If we compactify \( x^{10} \) on a circle of radius \( R \), we obtain the following bosonic degrees of freedom in ten dimensions.

1. The ten-dimensional metric, \( g_{\mu\nu} \) (\( \mu, \nu = 0, \ldots, 9 \)).
2. From \( g_{10\mu} \) we obtain a vector gauge field. This is identified with the Ramond–Ramond vector field of the IIA theory.
3. From \( C_{10\mu\nu} \) we obtain an antisymmetric tensor field, identified with the antisymmetric tensor, \( B_{\mu\nu} \) of the NS–NS sector of the IIA theory.
4. From \( C_{\mu\nu\rho} \), we obtain the three-index antisymmetric tensor field of the R–R sector of the IIA theory.
5. From \( g_{10,10} \) we obtain a scalar field in ten dimensions, the dilaton of the IIA theory. Note that this mode corresponds to the radius, \( R \), of the eleventh dimension.

Now consider the action. We will examine just the bosonic terms. These are constructed in terms of the curvature tensor, the three-index antisymmetric tensor, and its corresponding four-index field strength, \( F \):

\[
\mathcal{L} = -\frac{1}{2\kappa^2} \sqrt{g} R - \frac{1}{48} \sqrt{g} F_{MNPQ}^2 - \frac{\sqrt{2} \kappa}{3456} \epsilon_{M_1 \ldots M_{10}}^{A_1 \ldots A_8} R_{11} A_\mu F_{M_1 \ldots M_8} F_{M_9 M_{10}} C_{M_0} R_{11}.
\]

(28.29)

As we indicated, the dimensional reduction of this theory gives the Lagrangian of the IIA theory in ten dimensions. It is convenient to parameterize the fields in terms of the vielbein, \( e^A_M \). Then:

\[
e^A_M = \begin{pmatrix} e^A_\mu & A_\mu \\ 0 & R_{11} \end{pmatrix}.
\]

(28.30)

Correspondingly, the metric has the structure:

\[
g_{MN} = e^A_M e_B^N \eta_{AB} = \begin{pmatrix} g_{\mu\nu} & R_{11} A_\mu \\ R_{11} A_\nu & R_{11}^2 \end{pmatrix}.
\]

(28.31)

If we simply plug these expressions into the Lagrangian, the coefficient of the Einstein, \( \mathcal{R} \), term, will be proportional to \( R \). In order to bring this Lagrangian to the
canonical, Einstein form, it is necessary to perform a Weyl rescaling of the metric. But instead, we will perform the rescaling so as to bring the action to “string frame.” In this frame, all of the NS–NS fields have a factor of $e^{-2\phi}$ out front, where $e^{-2\phi}$ is the string coupling (dilaton). In ten dimensions, $\sqrt{g} = e$ transforms like $(g_{\mu\nu})^5$ under an overall rescaling of the metric; $\mathcal{R}$ transforms like $(g_{\mu\nu})^{-1}$. So we need to rescale:

$$g_{\mu\nu} \rightarrow R_{11}^{-2/3} g_{\mu\nu}. \quad (28.32)$$

The three form, $C$, upon reduction, leads to various fields in ten dimensions. The components $C_{10\mu\nu}$ give the NS–NS two-form. The fields $C_{\mu\nu\rho}$ give the R–R three-form. The R–R one-form field arises from the $g_{10,\mu}$ components of the metric. The ten-dimensional action becomes:

$$S = S_{NS} + S_R \quad (28.33)$$

with

$$S_{NS} = \frac{1}{2} \int d^{10}x \, \sqrt{g} e^{-2\phi} \left( \mathcal{R} + (\nabla \phi)^2 - \frac{1}{2} H^2 \right) \quad (28.34)$$

$$I_R = - \int d^{10}x \, \sqrt{g} \left( \frac{1}{4} F^2 + \frac{1}{2 \times 4!} F_4^2 \right) - \frac{1}{4} F_4 \wedge F_4 \wedge B. \quad (28.35)$$

We have seen that, when the action is written this way, $R$ is related to the coupling of the ten-dimensional string theory. The Weyl rescaling, $g_{\mu\nu} \rightarrow R_{11}^{-3/4} g_{\mu\nu}$ gives an action with $R^3$ out front, i.e.

$$\mathcal{L} = R_{11}^{-3} \left( -\frac{1}{2} \mathcal{R} - \frac{3}{4} R^{-3/2} H^2_{\mu\nu\rho} - \frac{9}{16} \left( \frac{\partial_{\mu} R_{11}}{R_{11}} \right)^2 \right). \quad (28.36)$$

In this form, the unit of length is the string scale, $\ell_s$. So loops come with a factor of $R_{11}^3$ (the ultraviolet cutoff is $\ell_s^{-1}$). So we see that

$$g_s^2 = \frac{R_{11}^3}{\ell_{11}^3}. \quad (28.37)$$

We can derive this relation another way (not keeping $2\pi s$), which makes a more direct connection between eleven-dimensional supergravity and strings. The eleven-dimensional theory has membrane solutions. We will not exhibit these here, but this should not be too surprising: the three-form, $C_{MNO}$, couples naturally to membranes. The eleven-dimensional theory has only one scale, $\ell_{11}$, so the tension of the membranes is of order $\ell_{11}^{-3}$. We can wrap one of the coordinates of the membrane around the eleventh dimension. If the eleventh dimension is very small,
the result is a string propagating in ten dimensions, with a tension:

\[ T = \ell_{11}^{-3} R = \ell_s^{-2}. \]  

(28.38)

Now, again, the ten-dimensional gravitational coupling is related to \( \ell_{11} \) by

\[ G_{10} = \frac{\ell_{11}^9}{R_{11}}. \]  

(28.39)

So we find, again,

\[ g_s^2 = \frac{R_{11}^3}{\ell_{11}^3}. \]  

(28.40)

So we have our first piece of circumstantial evidence for the connection. Let’s turn now to the BPS spectrum. Consider, first, the eleven-dimensional supersymmetry algebra. Eleven-dimensional spinors can be decomposed into ten-dimensional spinors of definite chirality, with indices \( \alpha \) and \( \dot{\alpha} \). In this basis,

\[ \Gamma_{11} = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}. \]  

(28.41)

The eleven-dimensional momenta decompose into ten-dimensional momenta and \( p_{11} \) in an obvious way:

\[ \{ Q_\alpha, Q_{\dot{\alpha}} \} = \dot{p}_{\alpha,\dot{\alpha}} + p_{11} \delta_{\alpha,\dot{\alpha}}. \]  

(28.42)

From a ten-dimensional point of view, the last term is a central charge. In the presence of such a central charge, we can prove a BPS bound as we did for the monopole. This bound is saturated by the Kaluza–Klein modes of the graviton and the antisymmetric tensor field. What charge does this central charge correspond to in the IIA theory, and to which states do the momentum states correspond? It is natural to guess that this is one of the R–R charges. The simplest possibility is the charge associated with the one-form gauge field. The carriers of the one-form charge are \( D0 \)-branes. The \( D0 \)-branes are BPS states – they preserve half of the ten-dimensional supersymmetry. So states of definite eleven-dimensional momentum are states of definite \( D \)-brane charge. More precisely, localized states with \( N \) units of Kaluza–Klein momentum correspond to zero-energy bound states (so-called threshold bound states) of \( N \) \( D \)-branes.

There are numerous further tests of this duality. For example, if one compactifies the theory further, there are connections to IIB theory. There are also connections involving \( M5 \)-branes. But this discussion gives some flavor of the duality, and the evidence.
28.6.2 IIB self-duality

The IIB theory exhibits an interesting self-duality. We can understand this, first, from the Lagrangian. The Lagrangian for the NS–NS fields is the same as for the IIA theory. For the R–R fields, we have now zero and two, and four-form fields. The Lagrangian for these is similar, with appropriate indices, to that for the R–R fields of the IIA case. A careful examination shows that under the transformation \( \phi \rightarrow -\phi \) the Lagrangian goes into itself. At the classical level, the action is also invariant under shifts of the axion.

Grouping the dilaton, \( e^\phi \), and the Ramond–Ramond scalar, \( \theta \), into a complex field,

\[
\tau = \frac{4\pi i}{g_s} + \frac{\theta}{2\pi},
\]

it then is natural to conjecture that the underlying theory has an \( SL(2, \mathbb{Z}) \) symmetry similar to that of \( N = 4 \) Yang–Mills theory:

\[
\tau \rightarrow \frac{a\tau + b}{c\tau + d} \quad ad - bc = 1.
\]

Further evidence for this symmetry is obtained by studying BPS objects: the various branes of the theory. In the IIB theory, we have fundamental strings and \( D1 \)-branes; we also have \( D5 \)-branes. Under this duality, the fundamental strings are mapped into \( D1 \)-branes by the \( SL(2, \mathbb{Z}) \) transformations. Correspondingly, the \( H_3 \) form (which couples to fundamental strings) should be mapped into the \( F_3 \) form (which couples to \( D1 \) strings). The \( D3 \)-branes are associated with the gauge-invariant five-form field strength, which is self-dual, so we might expect the \( D3 \)-branes to be invariant. Study of the BPS formulae for these states lends support to these conjectures.

This leaves the \( D5 \)-branes. These couple to the Ramond–Ramond six-form form gauge field, which is associated with a seven-form field strength, which is in turn dual to the three form R–R field strength. In other words, the \( D5 \)-brane is a magnetic source for \( F_3 \). So we might expect these to be dual to something which is a magnetic source for the NS three form. This would be an NS 5-brane. Such an object can be constructed as a soliton of the ten-dimensional IIB supergravity theory. It plays an important role in understanding the duality of these theories. It also appears in other contexts. For example, in \( M \) theory, it is associated with a seven-form field strength, which is dual to the four-form field strength we have already encountered.
The $M5$ solution is:

\[ g_{mn} = e^{2\phi} \delta_{mn}; \quad g_{\mu \nu} = \eta_{\mu \nu} \]  
\[ H_{mno} = -\epsilon_{mno} p \partial_p \phi \]  
\[ e^{2\phi} = e^{2\phi(\infty)} + \frac{Q}{2\pi^2 r^2}. \]

Here $\mu, \nu$ are the coordinates tangent to the brane (they are the world-volume coordinates); $m, n \ldots$ are the coordinates transverse to the brane. The $SL(2, \mathbb{Z})$ duality of the IIB theory is quite intricate and beautiful. There are many subtle and interesting checks.

### 28.6.3 Type I–$O(32)$ duality

The duality between the Type I and $O(32)$ theories is particularly intriguing, as it is a duality between a theory with open and closed strings and a theory with closed strings only. It is also puzzling since the perturbative spectra of these theories, at the level of massive states, are quite different. The $O(32)$ heterotic theory contains towers of massive states in spinor representations; there is nothing like this in the perturbative spectrum of the Type I theory. By way of evidence, we can begin, again, with the effective Lagrangian. For the heterotic theory this can be written

\[ \int d^{10}x e^{-2\phi (R + |\nabla \phi|^2 + F^2 + dB^2)}. \]

Here $e^{-2\phi}$ is the dilaton field, and we have written the action in string frame. Consider, now, the transformation:

\[ g = e^\phi g'; \quad \phi = -\phi'. \]

This takes the action to:

\[ \int d^{10}x \sqrt{g}(e^{-2\phi'} (R + |\nabla \phi'|^2) + e^{-\phi'} F^2 + dB^2). \]

This is the action for the bosonic fields of the Type I theory. The closed string fields couple with $g^2$, while the open string fields couple with $g$. In the Type I theory, the antisymmetric tensor is an R–R field, and as a result, no factor of the coupling (the dilaton) appears out front of its kinetic term.

Now we can ask: how do the heterotic strings appear in the open string theory? Here, we might guess that these strings would appear as solitons. More precisely, these strings are just the $D1$-branes of the Type I theory. At weak coupling, the tension of these strings will behave as $1/g$, i.e. it will be quite large. In this sector, one can find states in spinorial representations of $O(32)$, arising from configurations
of $D1$–$D9$-branes. Most important, the $D1$-branes are BPS. As a result, they persist to strong coupling, and in this regime their tension is small. We will not explore the various subtle tests of this correspondence, but other features one can investigate include the identification of the winding strings of the heterotic theory.

Many other dualities among different string theories have been explored. These include an equivalence between heterotic string theory on a four-torus and Type IIA on $K3$, and equivalences of Calabi–Yau compactifications of the Type II theory and heterotic theory on $K3 \times T2$.

### 28.7 Strongly coupled heterotic string

In ten dimensions, we have seen that the strong coupling limit of the IIA theory is a theory whose low-energy limit is eleven-dimensional supergravity. The strong coupling limit of the IIB theory is again the IIB theory. The strong coupling limit of the $O(32)$ heterotic string is the Type I string. This still leaves the question: what is the strong coupling limit of the $E_8 \times E_8$ heterotic string? The answer is intriguing. It has some tantalizing connections to facts we see in nature. It also suggests different ways of thinking about compactifications – inklings of the large extra dimension and warped space pictures which we will discuss in the next chapter.

Horava and Witten recognized that the strong coupling limit of the heterotic string, like the IIA theory, is an eleven-dimensional theory. The theory is defined on an interval of radius $R_{11}$. The relation of $R_{11}$ to the string tension and coupling are exactly as in the IIA case. This means that as the coupling gets large, the interval becomes large. We will refer to the full eleven-dimensional space as the “bulk.” The fields propagating in the bulk are a full eleven-dimensional supergravity multiplet: graviton, gravitino and three-form field. At the end of the interval, there are two walls (Fig. 28.1). These walls are similar to orientifolds, in that they are not dynamical (there are no degrees of freedom corresponding to motion of the walls). The
low-lying degrees of freedom on each wall are those of a supersymmetric $E_8$ gauge theory: gauge bosons and gauginos in the adjoint representation. The Lagrangian has the structure of a bulk plus boundary term:

$$
S = -\frac{1}{2\kappa^2} \int d^{11}x \sqrt{g} R - \sum_{i=1}^{2} \frac{1}{8\pi} (4\pi \kappa^2)^{2/3} \int d^{10}x \sqrt{g} \text{Tr} F_i^2 + \cdots .
$$

(28.51)

Note that the gauge coupling is simply proportional to the sixth power of the eleven-dimensional Planck length.

Support for this picture comes from a variety of sources. First, there is a subtle cancellation of gauge and gravitational anomalies. Second, the long-wavelength limit of this theory is ten-dimensional gravity plus Yang–Mills theory, with the relation between the gauge and gravitational couplings appropriate to the heterotic string (this is one way to fix the coupling constants). Further compactifications provide further checks.

### 28.7.1 Compactification of the strongly coupled heterotic string

One puzzle in the phenomenology of the weakly coupled heterotic string concerns the value of the gauge coupling and the unification scale. In the MSSM, the unification scale is two orders of magnitude below the Planck scale. If we imagine that the unification scale corresponds to a scale of compactification, then

$$
\alpha_{\text{gut}} \propto \frac{g_s^2}{V}.
$$

(28.52)

If we treat the left hand side as fixed, then as $V$ becomes large, so does $g_s$. Plugging in the observed values, $g_s$ is quite large. As we will now show, the situation in the strong coupling limit is much different — and much more promising.

Consider compactification of the strongly coupled theory on a Calabi–Yau space. The full compact manifold, from the point of view of an eleven-dimensional observer, is the product of the interval times a Calabi–Yau space $X$. Such a configuration is an approximate solution of the lowest-order equations of motion. Even at the level of the classical equations of this theory, there are corrections arising from the coupling of bulk to boundary fields. These can be constructed in a power series expansion. Terms in the expansion grow with $R_{11}$, owing to the one-dimensional geometry in the eleventh dimension. They are proportional to $\kappa^{2/3}$, from the bulk–brane coupling in Eq. (28.51). On dimensional grounds, there is a factor of $R^{-4}$, where $r$ is the Calabi–Yau radius. The expansion parameter is thus

$$
\epsilon = \kappa^{2/3} R_{11}/R^4.
$$

(28.53)
We can readily obtain the relation between the four-dimensional and eleven-dimensional quantities. Using the string relations (here we will be careful about factors of 2 and $\pi$):

\[
G_N = \frac{e^{2\phi}(\alpha')^4}{64\pi V} \quad \alpha_{\text{gut}} = \frac{e^{2\phi}(\alpha')^3}{16\pi V}
\]

where $V$ is the volume of the compact space $X$, and the eleven-dimensional relations:

\[
G_N = \frac{\kappa^2}{16\pi^2 VR_{11}} \quad \alpha_{\text{gut}} = \frac{(4\pi \kappa^2)^{2/3}}{2V},
\]

we have:

\[
R_{11}^2 = \frac{\alpha_{\text{gut}}^3 V}{512\pi^4 G_N^2} \quad M_{11} = R^{-1} \left(2(4\pi)^{-2/3}\alpha_{\text{gut}}\right)^{-1/6}.
\]

where $R = V^{1/6}$. Putting in the “observed” value of $\alpha_{\text{gut}}$ and the four-dimensional Planck mass gives:

\[
R_{11}M_{11} = 18 \quad R = 2\ell_{11} = (3 \times 10^{16}) \text{ GeV}.
\]

The regime of validity of the strongly coupled description is the regime where $V$ and $R_{11}$ are large compared to $\ell_{11}$. We see that nature might well be in such a regime. If we evaluate the expansion parameter $\epsilon$, we find $\epsilon \sim 1$. Adopting the viewpoint that the ground state of string theory which describes nature should be strongly coupled, this, again, seems promising: the parameters of grand unification correspond to the point where the eleven-dimensional expansion is just breaking down, $\epsilon \approx 1$. This is in contrast to the weak coupling picture, which seems far from its range of validity.

Apart from this rather direct phenomenological application of string theory ideas, there are two new possibilities which this analysis suggests. First, some compact dimensions might be large compared to the Planck scale (or any fundamental scale). Second, in a case with a one-dimensional geometry, this dimension can be significantly warped, i.e. the metric need not be a constant. These ideas underlie the large extra dimension and Randall–Sundrum models of compactification, which we will encounter in the next chapter.

### 28.8 Non-perturbative formulations of string theory

We have seen that, at least in cases with a great deal of supersymmetry, we have a surprisingly large access to non-perturbative dynamics. But much of the evidence for the various phenomena we have described is circumstantial, matching actions and spectra in various regions of a given string moduli space. We lack a general,
non-perturbative formulation of the theory, analogous to, say, the lattice formulations of Yang–Mills theories which we encountered in Part 1. One might have hoped that there would be a string field theory, analogous to ordinary quantum field theories, but such a program is fraught with conceptual and technical difficulties. We have mentioned some of these. In this section, we will describe situations where one can give a complete non-perturbative description. These descriptions are specific to particular backgrounds: flat space in higher dimensions, and certain AdS spaces. In eleven dimensions, the flat space, supersymmetric theory can be described as an ordinary quantum mechanical system, while the theory compactified on an \( n \)-dimensional torus is described by a field theory in \( n + 1 \) space-time dimensions, up to \( n = 3 \). Quite generally, string theory (gravity) in AdS spaces is described by conformal field theories; this is known as the AdS–CFT correspondence. Both formulations exhibit what is believed to be a fundamental feature of any quantum theory of gravity: holography. The holographic principle asserts that the number of degrees of freedom of a quantum theory of gravity grows, not as the volume of the system, but as its area.

### 28.8.1 Matrix theory

We have seen that the strong coupling limit of the IIA theory is an eleven-dimensional theory, whose low-energy limit is eleven-dimensional supergravity. D0-branes were crucial in making the correspondence. The Kaluza–Klein states of the eleven-dimensional theory were bound states of D0-branes; states with momentum \( N/R_{11} \) corresponded to zero-energy (“threshold”) bound states of \( N \) D0-branes. The world-line theory of \( N \) D0-branes is ten-dimensional \( U(N) \) Yang–Mills theory reduced to zero dimensions. The action which describes this system is:

\[
S = \int dt \left[ -\frac{1}{g} \text{tr}(D_t X^i D_t X^j) + \frac{1}{2g} M_{11}^6 R_{11}^2 \text{tr}([X^i, X^j][X^i, X^j]) + \frac{1}{g} \text{tr}(i \theta^T D_t \theta + M_{11}^3 R_{11} \theta^T \gamma^i [X^i, \theta]) \right],
\]

(28.58)

where \( R_{11} \) is the eleven-dimensional radius, \( M \) is the eleven-dimensional Planck mass and \( g = 2R_{11} \). The \( X \)'s are the bosonic variables, \( X_I, I = 1, \ldots, 9 \); \( \theta \)'s are the fermionic coordinates. It is necessary to impose Gauss’s law as a constraint on states.

Classically and quantum mechanically, this system has a large moduli space, corresponding to configurations with commuting \( X^I \)'s. For large \( X^I \), the spectrum in these directions consists, in the language of quantum mechanics, of \( 9N \) free particles, and a set of oscillators with frequencies of order \( |\vec{X}| \). We can integrate out the fast degrees of freedom, obtaining an effective action for the low-energy degrees
Beyond weak coupling: non-perturbative string theory

of freedom, the $X^I$'s and their superpartners. The bosonic states are just momentum states for these particles. They are the states corresponding to the collective modes of the $D$-branes.

Banks, Fischler, Shenker and Susskind made the bold hypothesis of identifying these degrees of freedom, and the Lagrangian of Eq. (28.58), as the complete description of the eleven-dimensional theory, in the limit that $N \to \infty$. More precisely, the Hamiltonian following from the action of (28.58) is identified with the light cone Hamiltonian, and $N$ is identified with the light cone momentum, $P^+ = N/R$. In the large-$N$ limit, this becomes a continuous variable; it is necessary to take $R \to \infty$ at a suitable rate. The first step in this identification is to note that the spectrum of low-lying states of the matrix model is precisely that of the light cone supergravity theory. We have already noted that the states are labeled by a momentum nine-vector, $\vec{p}$. In addition, there are sixteen fermionic variables, the partners of the bosons. As in other contexts, we can define eight fermionic creation operators and eight fermionic destruction operators. From these we can construct a Fock space with 256 states, of which half are space-time bosons (integer spin), and half are fermions. This is just the correct number to describe a graviton and antisymmetric tensor in eleven dimensions, and their superpartners. The states transform correctly under the little group.

A more convincing piece of evidence comes from studying the $S$-matrix of the matrix theory. Consider, for example, graviton–graviton scattering. Integrating out the massive states of the theory gives an action involving derivatives of $x$. We won’t reproduce the detailed calculation here, but the basic behavior is easy to understand. One can compute the action from Feynman graphs, just as in field theory. With four external $X$'s, simple power counting gives an action, in coordinate space, behaving as:

$$L_I \approx \dot{X}^4 \int \frac{dk}{(k^2 + M^2)^4} \equiv c \frac{v^4}{M^7}.$$  \hspace{1cm} (28.59)

Here $M \propto |X| = R$, the separation of the gravitons. The four factors of $v$ correspond to the four derivatives in the graviton–graviton amplitude; $1/R^7$ is precisely the form of the graviton propagator in coordinate space. With a bit more work, one can show that one obtains precisely the four-graviton amplitude in eleven dimensions, for suitable kinematics.

$M$ theory compactified on an $n$-torus is described by an $n + 1$-dimensional field theory. We won’t argue this, but note that in this case the power counting is correct to give the right graviton–graviton scattering amplitude. If $n > 3$, however, the theory is non-renormalizable, and the description does not make sense. An alternative description can be formulated for dimensions down to six. The matrix model has been subjected to a variety of other tests. It turns out that the large-$N$ limit is not
necessary; for fixed $N$, one describes a discretized version of the light cone theory (DLCQ). One can actually derive this result, starting with the assumed duality between IIA theory and eleven-dimensional supergravity.

All of this is quite remarkable. Without even postulating the existence of ordinary space-time, we have uncovered space-time, and general relativity, in a simple quantum mechanics model. One interesting feature of these constructions is the crucial role played by supersymmetry. Without it, quantum effects would lift the flat directions and one would not have space-time – though one would still have a sensible quantum system. One might speculate that what we think of as space-time is not fundamental, but almost an accident, associated with the dynamics of particular systems. Lacking, however, a formulation for a realistic, non-supersymmetric system, this remains speculation.

### 28.8.2 The AdS/CFT correspondence

An equally remarkable equivalence arises in the case of string theory on AdS spaces. This connection was first conjectured by Maldacena, and is referred to as the AdS/CFT correspondence. It asserts that graviton theories in AdS spaces have a description in terms of conformal field theories on the boundary.

#### A little more general relativity: anti-de Sitter space

We could construct anti-de Sitter space by solving the Freedman equation with negative cosmological constant. Instead, we will adopt a more geometrical viewpoint. Starting with a flat $p + 3$-dimensional space, with metric:

$$
\begin{equation}
\begin{aligned}
ds^2 &= -dx_0^2 - dx_{p+2}^2 + \sum_{i=1}^{p+1} dx_i^2 \\
&= -dx_0^2 - dx_{p+2}^2 + \sum_{i=1}^{p+1} dx_i^2 
\end{aligned}
\end{equation}
$$

we consider the hyperboloid:

$$
\begin{equation}
x_0^2 + x_{p+2}^2 - \sum_{i=1}^{p+1} x_i^2 = R^2.
\end{equation}
$$

These coordinates can be parameterized in various ways. For example, one can take

$$
\begin{aligned}
x_0 &= R \cosh(\rho) \cos(\tau), \quad x_{p+2} = R \cosh(\rho) \sin(\tau) \\
x_i &= R \sinh(\rho) \Omega_i (i = 1, \ldots, p + 1; \quad \Omega_i = 1). 
\end{aligned}
$$

This automatically satisfies (28.61), and yields the metric:

$$
\begin{equation}
\begin{aligned}
ds^2 &= R^2(- \cosh^2 \rho d\tau^2 + d\rho^2 + \sinh^2 \rho d\Omega^2).
\end{aligned}
\end{equation}
$$
In making the correspondence, another parameterization is helpful. These cover one half of the hyperboloid

\[
x_0 = \frac{1}{2u}(1 + u^2(R^2 + \bar{x}^2 - t^2)); \quad x_{p+2} = Ru \\
x^i = Rux^i (i = 1, \ldots p) \\
x^{p+1} = \frac{1}{2u}(1 - u^2(R^2 - \bar{x}^2 + t^2)).
\]  
(28.64)

The metric is then:

\[
ds^2 = R^2 \left( \frac{du^2}{u^2} + u^2(-dt^2 + d\bar{x}^2) \right).
\]  
(28.65)

AdS has interesting features, which we will not fully explore here. There is a boundary at spatial infinity \((u = \infty)\). Light can reach the boundary in finite time, but not massive particles. In a cosmological context, negative cosmological constant leads not to an eternal AdS space but to a singularity. The last form of the metric will be useful in making the correspondence in a moment. The metric has isometries (symmetries); the group of isometries can be seen from the form of the hyperboloid and the underlying metric of the \(p + 3\)-dimensional space; it is \(SO(2, p + 1)\). This turns out to be the same symmetry as conformal symmetry in \(p + 1\) dimensions; this, again, is a crucial aspect of the AdS/CFT correspondence.

\textit{Maldacena's conjecture}

Maldacena originally discovered this connection for the case of string theory on \(AdS_5 \times S_5\). One suggestive argument starts by considering a set of \(N\) parallel \(D3\)-branes. We have discussed such configurations as open string configurations, but they can also be uncovered as solitonic solutions of the supergravity equations, here of the IIB theory. For these, the metric has the form:

\[
ds^2 = H(y)^{-1/2} dx^\mu dx_\mu + H(y)^{1/2}(dy^2 + y^2d\Omega_5^2) \\
F_{\mu\nu\rho\sigma\tau} = \epsilon_{\mu\nu\rho\sigma\tau\alpha} \partial^\alpha H.
\]  
(28.66)

Here the \(x^\mu\)'s are the coordinates tangent to the branes, while the \(y\)s (and their associated angles) are the transverse coordinates. The dilaton in this configuration is a constant; the other antisymmetric tensors vanish. The function \(H\), for \(N\) parallel branes, is

\[
H(y) = 1 + \sum_{i=1}^{N} \frac{4\pi g_s(\alpha')^2}{|y - \bar{y}_i|^4}.
\]  
(28.67)
This can be rewritten as:
\[
 ds^2 = \left(1 + \frac{L^2}{y^4}\right)^{-1/2} \eta_{\mu\nu} dx^\mu dx^\nu + \left(1 + \frac{L^2}{y^4}\right)^{1/2} (dy^2 + y^2 d\Omega_5^2). \tag{28.68}
\]

The parameter \( L \) is related to the string coupling, \( g_s \), the brane charge (number of branes) \( N \), and the string tension by:
\[
 L^4 = 4\pi g_s N(\alpha')^2. \tag{28.69}
\]

It is convenient to introduce a coordinate \( u = L^2/y \), and to take a limit where \( N \) and \( g_s \) are fixed, while \( \alpha' \to 0 \). The metric then becomes:
\[
 ds^2 = L^2 \left[ \frac{1}{u^2} \eta_{\mu\nu} dx^\mu dx^\nu + \frac{du^2}{u^2} + d\Omega_5^2 \right]. \tag{28.70}
\]

The terms involving \( u \) and \( x \) we have seen previously; this is the geometry of \( AdS_5 \). The remaining terms describe a five-sphere of radius \( L \).

Now from a string point of view, the low-energy limit of the system of \( N \) \( D3 \)-branes is described by \( N = 4 \) Yang–Mills theory. So we might, with Maldacena, conjecture that there is just such an equivalence. Not surprisingly, demonstrating this equivalence is not so simple. One needs to argue that on the string side, the bulk modes (graviton, antisymmetric tensors, and so on) decouple, as do the massive excitations of the open strings ending on the branes. One cannot argue this at weak coupling, and it would be surprising if one could; in that case, one could calculate any quantity in the gravity theory in a weak coupling perturbation expansion in the Yang–Mills theory. This is similar to the situation in the matrix model. There are, however (as in the matrix model), many quantities which are protected by supersymmetry, and quite detailed tests are possible, both in this case and for many other examples of the correspondence.

**Suggested reading**

Non-perturbative string dualities are discussed extensively in the second volume of Polchinski’s (1998) book. This provides an excellent introduction to \( D \)-branes. \( D \)-branes are treated at length in the text by Johnson (2003), as well. The reader may want to consult earlier papers on duality, especially Witten (1995). Matrix theory and the AdS/CFT correspondence are treated in several excellent pedagogical reviews (Bigatti and Susskind, 1997; Aharony et al., 2000; D’Hoker and Freedman, 2002), but the original papers are very instructive; see, for example, Banks et al. (1997); Seiberg (1997), Maldacena (1997), Witten (1998).
Exercises

(1) $D$-branes: for a stack of $N$ $D$-branes, write the open string mode expansions. Show that, for small separations, the spectrum looks like that of a Higgsed $U(N)$ field theory, with Higgs in the adjoint representation. In the light cone gauge, check the counting of supersymmetries for open strings and $D$-branes.

(2) Verify the construction of the bosonic terms in the ten-dimensional action from the dimensional reduction of the eleven-dimensional action.

(3) Verify that the NS5-brane is a solution of the ten-dimensional supergravity equations.

(4) Take the long-wavelength limit of the Horava–Witten theory. Write the Lagrangian in the ten-dimensional Einstein frame and verify that the gauge and gravitational couplings obey the relation appropriate to the heterotic string theory:

$$g^2_{\text{ym}} = 4\kappa^2 \alpha'^{-1}.$$  \hspace{1cm} (28.71)

(5) Calculate the effective action of the matrix model at one loop in more detail. Verify that treated in Born approximation, this yields the correct graviton–graviton scattering matrix element for the eleven-dimensional theory. You may find the background field method helpful for this computation.

(6) Check that the configuration of Eq. (28.66) solves the field equations of IIB supergravity in the case of a single brane. You may want to use some of the available programs for evaluating the curvature. Verify that, in the Maldacena limit, the metric can be recast as in Eq. (28.30). If one requires that the curvature of the AdS space is small, check that the $D$-brane theory is strongly coupled. Discuss the problem of decoupling.
Considerations of the sort we encountered in the previous chapter have inspired two approaches to physics beyond the Standard Model: large extra dimensions (ADD) and warped spaces (Randall–Sundrum). In this chapter we will provide a brief introduction to each.

29.1 Large extra dimensions: the ADD proposal

In string theory, it is natural to imagine that the compactification scale is not too much different from the Planck scale. The size of the compact space is typically a modulus, and if it is stabilized, one might expect it be stabilized at a value not much different than one, in string (and therefore Planck) units. In terms of our general discussion of moduli stabilization, this is precisely what we would expect: once the radius becomes very large, any potential, perturbative or non-perturbative, tends to zero.

But if we are willing to discard this prejudice, an extraordinary possibility opens up. Perhaps the extra dimensions are not Planck size, but much larger, even macroscopic? Arkani-Hamed, Dimopoulos and Dvali realized that from an experimental point of view, the limits on the size of such large compact dimensions are surprisingly weak. Allowing the extra dimensions to be large totally reorients our thinking about the nature of couplings and scales in string theory (or any underlying fundamental theory). Such a viewpoint places the hierarchy problem in a whole different light, perhaps allowing entirely different solutions than technicolor or supersymmetry.

Branes are crucial to this picture. The observed gauge couplings are small, but not extremely small. But in Kaluza–Klein theory and in weakly coupled string theories, they are related to the underlying scales in a clear way. For example, in the heterotic string:

\[ g_4^{-2} \cong g_s^{-2} M_s^6 R^6. \]

(29.1)
So if $g_4$ is fixed, as $R \to \infty$, $g_s \to \infty$. But even in a compactified theory, the gauge coupling on $D3$-branes is insensitive to the large volume. With more general branes, one has more intricate possibilities, depending on how the branes wrap the internal space. On the other hand, gravity becomes weak as $R$ becomes large:

$$G_N = \frac{1}{M_p^2} = \frac{1}{M_p^8 R^6} = \frac{g_s^2}{\ell_s^8 R^6}.$$  \hspace{1cm} (29.2)$$

Now if $g_s$ is fixed and of order one, as $R \to \infty$, the Planck length tends to zero.

So how large might we imagine $R$ could be? If we assume that $R$ is macroscopic or nearly so, then on distance scales smaller than $R$, the force of gravity will be that appropriate to a higher-dimensional theory. In $d$ space-time dimensions,

$$\text{Force}_g \sim \frac{1}{r^{d-2}}.$$  \hspace{1cm} (29.3)$$

Experiments currently probe possible modifications of the gravitational force law on scales of order millimeters or somewhat smaller. (Since the proposal of large extra dimensions was put forward, these limits have been significantly improved.)

If the scale of the large extra dimensions is of order millimeters, how large is the fundamental scale? This depends on the number of dimensions that are actually large. If there are a large extra dimensions, any others being comparable in size to the fundamental scale,

$$M_p^2 = M_{\text{fund}}^{2+a} R^a,$$  \hspace{1cm} (29.4)$$

or

$$M_{\text{fund}} = (M_p^2 R^{-a})^{1/(2+a)} R = M_p^{-1} (M_p/M_{\text{fund}})^{(2+a)/a}.$$  \hspace{1cm} (29.5)$$

A new viewpoint on the hierarchy problem arises by supposing that $M_{\text{fund}}$ is close to the scale of weak interactions, say

$$M_{\text{fund}} \sim 1 \text{ TeV}.$$  \hspace{1cm} (29.6)$$

Then we can use Eq. (29.5) to relate $R$ to the Planck scale and the weak scale. For example, if $a = 2$, $R \approx 0.01 \text{ cm}$! For larger $a$, it is smaller, but still dramatically large; for $a = 3$, for example, it is about $10^{-7}$ cm. But $a = 1$ would be, quite literally, astronomical in size, and is clearly ruled out by observations.

What is quite surprising is that it is difficult to rule out dimensions with size of order millimeters. Since the original proposal, there have been several experiments dedicated to improving the limits on deviations from Newtonian gravity at millimeter distances.

The possibility of large extra dimensions offers a different perspective on the hierarchy problem. The weak scale is fundamental; the issue is to understand why
the radius of the large dimensions is so large. One possibility which has been seriously considered is that there are some very large fluxes. For example, if $H_{MN}$ is a two-form associated with a $U(1)$ gauge field, and $\Sigma$ is some closed two-dimensional surface, we can have:

$$\int_{\Sigma} H_{MN} dx^M \wedge dx^N = N.$$ \hfill (29.7)

If the radius of the dimensions associated with $\Sigma$ is large, then

$$H \sim \frac{N}{R^2}.$$ \hfill (29.8)

The potential, in turn, receives a contribution behaving as $N^2/R^2$. If there is also a (positive) cosmological constant,

$$V = \Lambda R^2 + \frac{N^2}{R^2},$$ \hfill (29.9)

and assuming that $\Lambda$ is of order the fundamental scale,

$$R^4 \sim N^2 \ell_{\text{fund}}^{4}.$$ \hfill (29.10)

To obtain a sufficiently large radius in this way, then, requires an extremely large flux. There are some circumstances where such large pure numbers may not be required; supersymmetry and low dimensionality ($a = 2$) help.

For now, we will assume that somehow a large radius arises for dynamical reasons, and consider some of the other questions which, ultimately, such a picture raises.

(1) Proton decay: with no further assumptions about the theory, we would expect that baryon number violating operators would arise suppressed only by the TeV scale. It would then be necessary to suppress operators of very high dimension. One possible resolution of this problem is elaborate discrete symmetries. Another suggestion has been that the modes responsible for the different low-energy fermions might be very nearly orthogonal.

(2) Other flavor changing processes: for the same reason, flavor changing processes in weak interactions, processes like $\mu \rightarrow e + \gamma$, and the like pose a danger. One possible solution is a fundamental scale a few orders of magnitude larger than the weak scale. This raises the question of why the weak scale is small – the hierarchy problem again. Orthogonality of fermions, again, can help with many of these difficulties.

We turn, finally, to the phenomenology of large extra dimensions. Here there are exciting possibilities. If $R$ is large, the Kaluza–Klein modes are very light. They are very weakly coupled, but there are lots of them and little energy is required for their production. So consider inclusive production of Kaluza–Klein particles in an accelerator. In terms of $G_N = \kappa^2/8\pi$ the amplitude for emission of a Kaluza–Klein
particle is proportional to $\kappa$. For any given mode, then, the cross section behaves as $\sigma_n \sim G_N E^2$, where the $E^2$ factor follows from dimensional analysis. We need to sum over $n$—equivalently, to integrate over $a$-dimensional phase space. As a crude estimate, we can treat the amplitude as constant, and cut off the integration at $E$, so

$$\sigma_{\text{tot}} = R^a \int d^a k \sigma_k = G_N R^a E^{2+a}. \quad (29.11)$$

Recalling that $G_N = G_{\text{fund}} R^{-a}$, we see that the tower of Kaluza–Klein particles couples like a $4 + a$-dimensional particle—i.e. at high energies, the extra dimensions are manifest! The cross section exhibits exactly the behavior with energy one expects in $4 + a$ dimensions.

The actual processes which might be observed in accelerators are quite distinctive. One would expect to see, for example, production of high-energy photons accompanied by missing energy, with the cross section showing a dramatic rise with energy. Such signatures have already been used (as of this writing) to set limits on such couplings.

The production of Kaluza–Klein particles in astrophysical environments can be used to set limits on extra dimensions as well. For example, in the case of two large dimensions and fundamental scale of order 1 TeV, we saw that the scale of the Kaluza–Klein excitations—the inverse of the radius of the extra dimensions—is of order $10^{-12}$ GeV, so such particles are easy to produce. Like axions, they could be readily produced in stars.

### 29.2 Warped spaces: the Randall–Sundrum proposal

Having entertained the possibility that some compact dimensions of space might be very large, one might wonder why the extra dimensions should be flat. The Horava–Witten theory provides a model. Taking the formulas of this theory literally, we have seen that if this theory describes nature, the eleventh dimension is quite large in fundamental units. The metric of this dimension is significantly distorted; we might say that it is warped. This is not surprising. The geometry is essentially one-dimensional. Green’s functions for the fields grow linearly with distance. One of the appealing features of the Horava–Witten proposal is that the dimensions are just large enough that the distortion of the geometry is of order one.

Randall and Sundrum have made a more radical proposal: they argue that the warping might be enormous, and might account for the large hierarchy between the weak scale and the Planck scale. In the simplest version of their model, there is again one extra dimension; call its coordinate $0 < \phi < \pi$. The model contains two branes, one at $\phi = 0$, one at $\phi = \pi$. The tensions of the two branes are taken to be equal and opposite. One imagines that the Standard Model fields propagate...
on one brane, the “visible sector” brane, while some other, hidden sector fields propagate on the other. The action is:

$$ S = S_{\text{grav}} + S_{\text{vis}} + S_{\text{hid}}. $$  \hfill (29.12)

The bulk gravitational action, $S_{\text{grav}}$, includes a cosmological constant term:

$$ S_{\text{grav}} = \int d^4 x \int d\phi \sqrt{-G} [-\Lambda + 2M^3R], $$  \hfill (29.13)

where $M$ is the five-dimensional Planck mass. The brane actions are:

$$ S_{\text{vis}} = \int d^4 x \sqrt{-g_{\text{vis}}} [\mathcal{L}_{\text{vis}} - \Lambda_{\text{vis}}] \quad S_{\text{hid}} = \int d^4 x \sqrt{-g_{\text{hid}}} [\mathcal{L}_{\text{hid}} - \Lambda_{\text{hid}}]. $$  \hfill (29.14)

Here we have separated off a brane tension term on each brane; we have also distinguished the bulk five-dimensional metric, $G_{MN}$, from the metrics on each of the branes, $g_{\mu\nu}$. This has the structure of a gravitational problem in five dimensions, with $\delta$-function sources at $\phi = 0, \pi$. Einstein’s equations are:

$$ \sqrt{-G} \left( R_{MN} - \frac{1}{2} G_{MN} R \right) = -\frac{1}{4M^3} \left[ \Lambda \sqrt{-G} G_{MN} + \Lambda_{\text{vis}} \sqrt{-g_{\text{vis}}} g_{\mu\nu}^{\text{vis}} \delta_M^\mu \delta_N^\nu \delta(\phi - \pi) 
+ \Lambda_{\text{hid}} \sqrt{-g_{\text{hid}}} g_{\mu\nu}^{\text{hid}} \delta_M^\mu \delta_N^\nu \delta(\phi) \right]. $$  \hfill (29.15)

Now one makes an ansatz for the metric, which leads to warping:

$$ ds^2 = e^{-2\sigma(\phi)} \eta_{\mu\nu} dx^\mu dx^\nu + r_c^2 d\phi^2. $$  \hfill (29.16)

Plugging in the ansatz, Eq. (29.16), one obtains equations for $\sigma$:

$$ \frac{6\sigma''}{r_c^2} = -\frac{\Lambda}{4M^3} \quad \frac{3\sigma''}{r_c^2} = \frac{\Lambda_{\text{hid}}}{4M^3r_c} \delta(\phi - \pi) + \frac{\Lambda_{\text{vis}}}{4M^3r_c} \delta(\phi - \pi). $$  \hfill (29.17)

This is solved by:

$$ \sigma = r_c |\phi| \sqrt{-\frac{\Lambda}{24M^3}} $$  \hfill (29.18)

provided that the following conditions on the $\Lambda$s hold:

$$ \Lambda_{\text{hid}} = \Lambda_{\text{vis}} = 24M^3 k \quad \Lambda = -24M^3 k^3. $$  \hfill (29.19)

In this case, the metric varies exponentially rapidly. Note that $r_c$ does not need to be terribly large in order that one obtain an enormous hierarchy. One might worry, though, about the identification of the graviton. It turns out that the metric has zero modes:

$$ ds^2 = e^{-2kr_c|\phi|} [\eta_{\mu\nu} + \tilde{h}_{\mu\nu}(x) dx^\mu dx^\nu + T^2(x)d\phi^2], $$  \hfill (29.20)
where $T^2$ represents a variation of $r_c$, and is usually referred to as the radion, and $\tilde{h}_{\mu\nu}$ is the four-dimensional metric. If one substitutes in the action, one finds:

$$S = \int d^4x \int d\phi 2M^3 r_c e^{-2kr_c|\phi|} \sqrt{-g} \tilde{R}.$$  \hspace{1cm} (29.21)

From this we can read off the effective Planck mass:

$$M^2_p = M^3 r_c \int d\phi e^{-2kr_c|\phi|} = \frac{M^3}{k} \left[ 1 - e^{-2kr_c} \right].$$  \hspace{1cm} (29.22)

So the four-dimensional Planck scale is comparable to the fundamental five-dimensional scale.

To see that the physical masses on the visible brane are small, consider the visible sector action for a scalar particle:

$$S_{\text{vis}} = \int d^4x \sqrt{-g} e^{-4kr_c} \left[ \tilde{g}_{\mu\nu} e^{2kr_c} |D_{\mu}\phi|^2 - \lambda (|\phi|^2 - v_0^2)^2 \right].$$  \hspace{1cm} (29.23)

Rescaling $\phi \rightarrow e^{kr_c} \pi \phi$, we have:

$$S_{\text{vis}} = \int d^4x \sqrt{-g} \left[ \tilde{g}_{\mu\nu} |D_{\mu}\phi|^2 - \lambda (|\phi|^2 - e^{-2kr_c} v_0^2)^2 \right].$$  \hspace{1cm} (29.24)

so the scale is indeed exponentially smaller than the scale on the other brane.

There are many questions one can ask about this structure.

(1) How robust is this sort of localization of gravity?
(2) How do higher excitations, e.g. bulk fields, interact with the fields on the brane? Is the hierarchy stable? (The answer is yes.)
(3) Does this sort of warping arise in string theory? Again, the answer is yes, though the details look different.
(4) As in the case of large extra dimensions, if this picture makes sense, there are many excitations on the branes. Higher-dimension operators are suppressed only by the TeV scale. As there, one has to ask: how does one understand conservation of baryon number? Other flavor changing processes? Neutrino masses? Precision electroweak physics? Answers have been put forward to all of these questions, but they remain suitable subjects for research.
(5) Assuming the above problems are resolved, what are the experimental signals for such warping? As in the case of large extra dimensions, one wants to focus on the additional degrees of freedom associated with bulk fields and the brane. In this case, unlike the case of large extra dimensions, the Kaluza–Klein states are not dense. Instead, the low-lying states have masses and spacings of order the TeV scale. Their couplings are not of gravitational strength, but instead scaled by inverse powers of the scale of the visible sector brane.

Finally, there are other variants of the Randall–Sundrum proposal which have been put forward. Perhaps the most interesting is one in which space is not
compactified at all, but simply warped, with gravity localized on the visible brane. These ideas suggest a rich set of possibilities for what might underlie a quantum theory of gravity. Some of these features – the exponential warping of the metric, in particular – have been observed in string theory, but many, at least to date, have not. This is a potentially important area for further research.

Suggested reading

The original paper of Arkani-Hamed et al. (1999) is quite clear and comprehensive, as is the paper of Randall and Sundrum (1999). The phenomenology of the Randall–Sundrum models is explored by Davoudiasl et al. (2000).

Exercise

(1) Verify the Randall–Sundrum solution of Eq. (29.15).
As this book is being completed, the Large Hadron Collider (LHC) at CERN, and its two large detectors, ATLAS and CMS, are nearing completion. The center of mass energy at this machine will be large, about 14 TeV. The center of mass energies of the partons – the quarks and gluons – within the colliding protons will be larger than 1 TeV. The luminosity will also be very large. As a result, if almost any of the ideas we have described for understanding the hierarchy problem in Part 1 of this book are correct, evidence should appear within a few years. For example, if the hypothesis of low-energy supersymmetry is correct, we should see events with large amounts of missing energy, and signatures such as multiple leptons. Large extra dimensions should be associated with rapid growth of cross sections for various processes, again with missing energy; the warped spaces suggested by Randall and Sundrum should be associated with the appearance of massive resonances. Technicolor, similarly, should lead to broad resonances. Assuming some underlying technicolor model can satisfy constraints from flavor physics and precision electroweak measurements, one might expect to find some number of light (compared with 1 TeV), pseudo-Goldstone bosons, many with gauge quantum numbers. If any of these phenomena occur, distinguishing among them in the complicated environment of a hadron machine will be challenging. It is conceivable that there will be competing explanations, and that choosing between them will require a very high-energy electron–positron colliding beam machine. Such a machine is under consideration by a consortium of nations, and is referred to as the International Linear Collider, or ILC. Hopefully in later editions of this book, it will be possible to focus on real experimental results, rather than a range of theoretical speculation.

Before the data rolls in, we might hope to select among these possibilities, or perhaps discover some crucial idea – and possible set of phenomena – that we are missing. Here, string theory might help. Many of the ideas for Beyond the Standard Model Physics require phenomena which can only be understood within
a quantum theory of gravity. This is certainly true of large extra dimensions or Randall–Sundrum.

We have discussed many aspects of string theory, but as far as the world about us and the experiments which explore it, we have left things in a rather unsettled state. We have seen that string theories have many of the features we might hope for from nature. We have exhibited ground states – more precisely, approximate moduli spaces – with many of the features of the Standard Model: the observed gauge groups, repetitive generations of quarks and leptons, calculable gauge and Yukawa couplings, and more. But it is not clear how to make sharp predictions. There are vast numbers of moduli spaces with the wrong features: the wrong number of dimensions, too much supersymmetry, the wrong gauge group and matter content, and we have not offered a dynamical mechanism or principle which might select among them. Not only are there discrete choices, but there are continuous ones as well, associated with the moduli. We have seen how potentials for the moduli arise, but we have not offered any idea for how stable or metastable vacua might arise, other than to note that such states will typically lie at strong coupling, where they are inaccessible to analysis. Note that our discussion of strong–weak coupling duality, by itself, does not help with this problem; our general arguments show that one cannot find stable vacua at arbitrarily weak coupling in any description.

For a long time, string theorists hoped for some deus ex machina which might resolve this conundrum. Some have imagined that one would simply find some new type of string model or construction which would not suffer from these difficulties, perhaps leading uniquely to the Standard Model at low energies. Developments in string duality have suggested an alternative picture: there might exist a vast number of isolated, stable or metastable states of the theory, with little or no supersymmetry. These states seem to have a distribution of values of couplings, mass scales and cosmological constant. There may be an exponentially large or even infinite number of them.

To understand how these come about, we return, again, to the IIB theories. In these theories, there are two three-form gauge fields, one arising from the NS–NS sector, the other in the R–R sector; denote these $H$ and $F$. If one compactifies on a Calabi–Yau space, it is possible to have non-trivial backgrounds for these fields. One can define three-form fluxes by integrating these over non-trivial three cycles. The number of such cycles, we have learned, is $h_{2,1}$. The fluxes are quantized, by an argument identical to Dirac’s. There are also constraints on the values of fluxes, resulting from absence of anomalies (violation of Gauss’s law). In the presence of fluxes, we might expect the system to have a non-trivial energy; this energy is a function of the values of the moduli, so there is a potential for the moduli. This potential can be described in terms of a superpotential. It turns out that there is a
30 Coda: Where are We Headed?

simple formula for the superpotential:

$$W = \int G_3 \wedge \Omega,$$

where $G_3 = F_3 - \tau H_3$ and $\omega$ is the covariantly constant three-form. One can obtain explicit formulas in the case of compactification of the IIB theory on a torus. This expression depends on the complex structure moduli, $z$, but not on the Kahler moduli, $\rho$.

The equations $D_z W = 0$ generically fix the complex structure moduli and the dilaton but not the Kahler moduli. But the superpotential of Eq. (30.1) is not exact, and can receive non-perturbative corrections. These can lead to a potential for the Kahler moduli. Logically, we can organize the analysis by first integrating out the complex structure moduli and the dilaton, leaving a superpotential for the Kahler modulus, $\rho$, of the form:

$$W_\rho = W_0 + e^{-c\rho}.$$  \hfill (30.2)

The Kahler potential, on the other hand, for large $\rho$ and weak coupling should not be too different than its tree-level form:

$$K = -3 \ln(\rho + \rho^*).$$  \hfill (30.3)

If $W_0$ is small, it is not hard to see that the potential has a supersymmetric stationary point at

$$\rho \approx -c \ln(W_0).$$  \hfill (30.4)

But why should $W_0$ be small? The answer is that, in general, it isn’t, but there are many possible choices of flux, and so there are many different possible states with different values of $W_0$. In this construction, the number of possible flux choices which permit a supersymmetric low-energy theory for $\rho$ is finite but extremely large. One can understand this by thinking of a $b$-dimensional vector of integers, $\vec{N}$, representing the fluxes, constrained by $|\vec{N}|^2 < L^2$. The number of possible flux choices is then the volume of a $b$-sphere of radius $L$, or of order

$$N \approx L^b.$$  \hfill (30.5)

In interesting Calabi–Yau compactifications, $L$ and $b$ can be of order 100s.

If we suppose that $W_0$ is distributed more or less randomly among these states, we might expect that the probability of finding $W_0$ at small $W_0$ would be roughly uniform with $W_0$ as a complex variable, i.e. $\int d^2 W_0 P(W_0)$, with $P(W_0)$ constant. Numerical studies suggest that this is indeed the case.

Other quantities will also vary across the landscape. One can get gauge groups, for example, by including branes in these configurations. There will be, then, a
distribution of groups and couplings. Perhaps not surprisingly, the distribution of \textit{gauge couplings}, at small gauge coupling, is typically flat in $g^2$. One might expect to find supersymmetry broken dynamically or through brane configurations. There is also a vast array of states – perhaps infinite, where supersymmetry is broken already by the classical superpotential for the complex structure moduli, i.e. one cannot solve the set of equations $D_zW = 0$.

This is compatible with many of our ideas for thinking about the hierarchy problem. In supersymmetry, technicolor, and the Randall–Sundrum approaches, one argues that it is reasonable to have exponentially small scales, because it is reasonable to think that couplings should be small, but not much smaller than one. Why this should be so is unclear. If there is a unique underlying theory, for example, the couplings are whatever they are. But within this landscape, there is a distribution, which would seem to motivate just the sorts of ideas we have explored.

Much work is going into mapping the features of this landscape. Many types of states have been explored and their statistics at least partially understood, including states with and without supersymmetry, with various gauge groups, and the like. From these studies, it seems plausible that there are some – possibly many – states in the landscape with the low-energy features of the Standard Model. This naturally raises several related questions.

(1) Are typical states with the features of the Standard Model characterized by things we might hope to measure, such as large extra dimensions or supersymmetry?
(2) Why do we find ourselves in a state which looks like ours does?

If one can answer these questions, one might hope to make real predictions. It is, at this writing, too early to answer the first, though one can enumerate some of the issues. For example, if there are comparable numbers of supersymmetric and non-supersymmetric states, it might be that there are more supersymmetric states with a large hierarchy of states than non-supersymmetric ones. If there are vastly more non-supersymmetric states, it might be that technicolor or warping are the most common ways of obtaining large hierarchies.

If the landscape really exists with the sorts of properties we are attributing to it, it seems likely that the answer to the second question is, in part, \textit{environmental}. The issue is posed most starkly by the cosmological constant. The distribution of cosmological constants is not likely to peak at the very tiny but non-zero observed value. On the other hand, Weinberg, and also Banks, pointed out long ago that if the cosmological constant were much larger than observed (perhaps a factor of 10), galaxies would not form. The problem is that the exponential expansion of the universe would begin before the perturbations from inflation became non-linear. Given that structure formed when the universe was about 1/20 of its present age, a cosmological constant far larger than the present energy density would be
problematic. This argument predicted a cosmological constant in the observed range.

The idea that some quantities are determined by environmental considerations, or *anthropic* conditions, is quite controversial. At one level, one can ask what would happen if several quantities, such as the parameters of the inflationary potential, were allowed to vary. At another, this argument requires that the universe, somehow in its history, sampled all of the different possible states. Within present ideas about inflation, it is not clear whether this is possible. Finally, even granting the first two points, this argument rests on the requirement of observers to determine at least some of the laws of nature. Some physicists argue that this is no different than saying that we find ourselves on a planet at a certain distance from a star because, otherwise, the planet could not support life; they point out that through much of human history, the Earth–Sun distance was viewed as fundamental. But many physicists find this troubling. At this writing, however, it is fair to say that this is by far the most plausible explanation we have of the value of $\Lambda$.

Hopefully, the reader who has worked patiently through this book, has been left with challenging questions, and the skills to attack them. As the LHC turns on, as further progress is made in understanding how quantum gravity might be reconciled with much lower-energy physics, we may be at the threshold of understanding what lies beyond the Standard Model.

**Suggested reading**

Weinberg’s argument for the cosmological constant appears in his 1989 paper. The landscape picture we have described here was first put forward by Bousso and Polchinski (2000) and Feng *et al.* (2001), and formulated most sharply in string theory by Kachru *et al.* (2003). Some statistical studies, which significantly elucidate the possible meaning of the landscape, appear in Ashok and Douglas (2004).
Part 4

The appendices
Appendix A

Two-component spinors

The massless Dirac equation simplifies dramatically in the case that the fermion mass is zero. The equation

$$\slashed{D} \psi = 0$$  \hspace{1cm} (A1)

has the feature that if $\psi$ is as solution, so is $\gamma_5 \psi$:

$$\slashed{D} (\gamma_5) = 0.$$  \hspace{1cm} (A2)

The matrices

$$P_{\pm} = \frac{1}{2} (1 \pm \gamma_5)$$  \hspace{1cm} (A3)

are projectors,

$$P_{\pm}^2 = P_{\pm} \quad P_+ P_- = P_- P_+ = 0.$$  \hspace{1cm} (A4)

To understand the physical significance of these projectors, it is convenient to use a particular basis for the Dirac matrices, often called the chiral or Weyl basis:

$$\gamma^\mu = \begin{pmatrix} 0 & \sigma^\mu \\ \bar{\sigma}^\mu & 0 \end{pmatrix},$$  \hspace{1cm} (A5)

where

$$\sigma^\mu = (1, \vec{\sigma}) \quad \bar{\sigma}^\mu = (1, -\vec{\sigma}).$$  \hspace{1cm} (A6)

In this basis,

$$\gamma_5 = i \gamma^0 \gamma^1 \gamma^2 \gamma^3 = \begin{pmatrix} -1 & 0 \\ 0 & 1 \end{pmatrix},$$  \hspace{1cm} (A7)

so

$$P_+ = \begin{pmatrix} 0 & 0 \\ 0 & 1 \end{pmatrix} \quad P_- = \begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix}.$$  \hspace{1cm} (A8)

We will adopt some notation, following the text by Wess and Bagger:

$$\psi = \begin{pmatrix} \chi_\alpha \\ \phi^{*\alpha} \end{pmatrix}.$$  \hspace{1cm} (A9)
Correspondingly, we label the indices on the matrices $\sigma^\mu$ and $\bar{\sigma}^\mu$ as

$$\sigma^\mu = \sigma^\mu_{\alpha \dot{\alpha}}, \quad \bar{\sigma}^\mu = \bar{\sigma}^\mu_{\beta \dot{\beta}}.$$  \hspace{1cm} (A10)

This allows us to match upstairs and downstairs indices, and will prove quite useful. The Dirac equation now becomes:

$$i \sigma^\mu_{\alpha \dot{\alpha}} \partial^\mu \phi^* = 0 \quad i \bar{\sigma}^\mu_{\beta \dot{\beta}} \partial^\mu \chi = 0.$$  \hspace{1cm} (A11)

Note that $\chi$ and $\phi^*$ are equivalent representations of the Lorentz group; $\chi$ and $\phi$ obey identical equations. We may proceed by complex conjugating the second equation in Eq. (A11), and noting $\sigma_{\alpha \dot{\alpha}} \sigma^*_{\alpha \dot{\alpha}} = \bar{\sigma}^\mu.$

Before discussing this identification in terms of representations of the Lorentz group, it is helpful to introduce some further notation. First, we define complex conjugation to change dotted to undotted indices. So, for example,

$$\phi^*_{\alpha \dot{\alpha}} = (\phi^*_{\beta \dot{\beta}}).$$  \hspace{1cm} (A12)

Then we define the antisymmetric matrices $\epsilon_{a \dot{b}}$ and $\epsilon^{a \dot{b}}$ by:

$$\epsilon_{12} = 1 = -\epsilon_{21} \quad \epsilon_{a \dot{b}} = -\epsilon^{a \dot{b}}.$$  \hspace{1cm} (A13)

The matrices with dotted indices are defined identically. Note that, with upstairs indices, $\epsilon = i \sigma_2$, $\epsilon_{a \dot{b}} \epsilon^{b \dot{a}} = \delta_{a \dot{b}}$. We can use these matrices to raise and lower indices on spinors. Define $\phi_{\alpha} = \epsilon_{a \dot{b}} \phi_{b \dot{a}}$, and similar for dotted indices. So

$$\phi_{\alpha} = \epsilon_{a \dot{b}} (\phi^{b \dot{a}})^*.$$  \hspace{1cm} (A14)

Finally, we will define complex conjugation of a product of spinors to invert the order of factors, so, for example, $(\chi_{\alpha} \phi_{\beta})^* = \phi_{\beta}^{* \dot{\alpha}} \chi_{\dot{\alpha}}$.

With this in hand, the reader should check that the action for our original four-component spinor is:

$$S = \int d^4 x L = \int d^4 x \left( i \chi_{\alpha}^{* \dot{\alpha}} \bar{\sigma}^\mu_{\mu \dot{\alpha}} \partial^\mu \chi_{\alpha} + i \phi^{a \dot{\alpha}} \sigma^\mu_{a \dot{\alpha}} \partial^\mu \phi^*_{\alpha \dot{\alpha}} \right)$$

$$= \int d^4 x L' = \int d^4 x \left( i \chi_{\alpha}^{\dot{\alpha}} \sigma^\mu_{\alpha \dot{\alpha}} \partial^\mu \chi_{\alpha} + i \phi_{a \dot{\alpha}} \sigma^\mu_{a \dot{\alpha}} \partial^\mu (\phi^{* \dot{\alpha}}) \right).$$  \hspace{1cm} (A15)

At the level of Lorentz-invariant Lagrangians or equations of motion, there is only one irreducible representation of the Lorentz algebra for massless fermions.

Two-component fermions have definite helicity. For a single-particle state with momentum $\tilde{p} = p \hat{z}$, the Dirac equation reads:

$$p(1 \pm \sigma_z) \phi = 0.$$  \hspace{1cm} (A16)

Similarly, the reader should check that the antiparticle has the opposite helicity.

It is instructive to describe quantum electrodynamics with a massive electron in two-component language. Write

$$\psi = \begin{pmatrix} e \\ \bar{e}^* \end{pmatrix}.$$  \hspace{1cm} (A17)

In the Lagrangian, we need to replace $\partial^\mu$ with the covariant derivative, $D^\mu$. Note that $e$ contains annihilation operators for the left-handed electron, and creation operators for the corresponding antiparticle. Note also that $\bar{e}$ contains annihilation operators for a particle with the opposite helicity and charge of $e$, and $\bar{e}^*$, and creation operators for the corresponding antiparticle.
The mass term, $m \bar{\psi} \psi$, becomes:

$$m \bar{\psi} \psi = me^a \bar{e}_a + me^*_{\dot{a}} \bar{e}^{*\dot{a}}.$$  \hspace{1cm} (A18)

Again, note that both terms preserve electric charge. Note also that the equations of motion now couple $e$ and $\bar{e}$.

It is helpful to introduce one last piece of notation. Call

$$\psi \chi = \psi^a \chi_a = -\psi_{\dot{a}} \chi^{\dot{a}} = \chi^a \psi_a = \chi \psi.$$  \hspace{1cm} (A19)

Similarly,

$$\psi^* \chi^* = \psi^*_{\dot{a}} \chi^{*\dot{a}} = -\psi^{*\dot{a}} \chi^*_{\dot{a}} = \chi^*_{\dot{a}} \psi^{*\dot{a}} = \chi^* \psi^*.$$  \hspace{1cm} (A20)

Finally, note that with these definitions,

$$(\chi \psi)^* = \chi^* \psi^*.$$  \hspace{1cm} (A21)
Appendix B
Goldstone’s theorem and the pi mesons

It is easy to prove Goldstone’s theorem for theories with fundamental scalar fields. But the theorem is more general, and some of its most interesting applications are in theories without fundamental scalars. We can illustrate this with QCD. In the limit that there are two massless quarks (i.e. in the limit that we neglect the mass of the $u$ and $d$ quarks), we can write the QCD Lagrangian in terms of spinors

$$\Psi = \begin{pmatrix} u \\ d \end{pmatrix}$$  \hspace{1cm} (B1)

as

$$\mathcal{L} = \bar{\psi} i \gamma^\mu D_\mu \psi - \frac{1}{4} F_{\mu \nu}^2.$$  \hspace{1cm} (B2)

This Lagrangian has symmetries:

$$\Psi \rightarrow e^{i \omega^a \tau^a} \Psi \hspace{1cm} \bar{\Psi} \rightarrow e^{i \omega^a \tau^a} \bar{\Psi}.$$  \hspace{1cm} (B3)

($\tau^a$ are the Pauli matrices). In the limit that two quarks are massless, QCD is thus said to have the symmetry $SU(2)_L \times SU(2)_R$.

So writing a general four-component fermion as

$$q = \begin{pmatrix} q \\ \bar{q}^* \end{pmatrix},$$  \hspace{1cm} (B4)

the Lagrangian has the form:

$$\mathcal{L} = i \bar{\Psi} \sigma^\mu D_\mu \Psi^* + i \bar{\bar{\Psi}} \sigma^\mu D_\mu \bar{\Psi}^*.$$  \hspace{1cm} (B5)

In this form, we have two separate symmetries:

$$\Psi \rightarrow e^{i \omega^a \tau^a} \Psi \hspace{1cm} \bar{\Psi} \rightarrow e^{i \omega^a \tau^a} \bar{\Psi}.$$  \hspace{1cm} (B6)

Written in this way, it is clear why the symmetry is called $SU(2)_L \times SU(2)_R$.

Now it is believed that in QCD, the operator $\bar{\Psi} \Psi$ has a non-zero vacuum expectation value, i.e.

$$\langle \bar{\Psi} \Psi \rangle \approx (0.3 \text{GeV})^3 \delta_{ff'}.$$  \hspace{1cm} (B7)

This is in four-component language; in two-component language this becomes:

$$\langle \bar{\Psi}_f \Psi_{f'} + \bar{\Psi}_{f'}^* \Psi_f^* \rangle \neq 0.$$  \hspace{1cm} (B8)

487
This leaves ordinary isospin, the transformation, in four-component language, without the \( \gamma_5 \), or, in two-component language, with \( \omega_a^L = -\omega_a^R \), unbroken.

But there are three broken symmetries. Correspondingly, we expect that there are three Goldstone bosons. To prove this, write

\[
\mathcal{O} = \bar{\Psi} \psi; \quad \mathcal{O}^a = \bar{\Psi} \gamma^5 \frac{\tau^a}{2} \psi. \tag{B9}
\]

Under an infinitesimal transformation,

\[
\delta \mathcal{O} = 2i \omega^a \mathcal{O}^a; \quad \delta \mathcal{O}^a = i \omega^a \mathcal{O}. \tag{B10}
\]

In the quantum theory, these becomes the commutation relations:

\[
[Q^a, \mathcal{O}] = 2i \omega^a \mathcal{O}; \quad [Q^a, \mathcal{O}^b] = i \delta^{ab} \mathcal{O}. \tag{B11}
\]

\( Q^a \) is the integral of the time component of a current. To see that there must be a massless particle, we study

\[
0 = \int d^4x \partial_\mu \left[ \langle \Omega \vert T(j^{\mu a}(x) \mathcal{O}^b(0)) \vert \Omega \rangle e^{-ip \cdot x} \right] \tag{B12}
\]

(this just follows because the integral of a total derivative is zero). We can evaluate the right-hand side, carefully writing out the time-ordered product in terms of \( \theta \) functions, and noting that \( \partial_0 \) on the \( \theta \) functions gives \( \delta \)-functions:

\[
0 = \int d^4x \langle \Omega \mid j^{\mu a}(x) \mathcal{O}^b(0) \rangle \delta(x^0) \vert \Omega \rangle e^{-ip \cdot x} - ip_\mu \times \int d^4x \langle \Omega \mid T(j^{\mu a}(x) \mathcal{O}^b(0)) \vert \Omega \rangle. \tag{B13}
\]

Now consider the limit \( p^\mu = 0 \). The first term on the right-hand side becomes the matrix element of \( [Q^a, \mathcal{O}^b(0)] = \mathcal{O}(0) \). This is non-zero. The second term must be singular, then, if the equation is to hold. This singularity, as we will now show, requires the presence of a massless particle. For this we use the spectral representation of Green’s function. In general, a pole can arise at zero momentum only from a massless particle. To understand this singularity we introduce a complete set of states, and, say for \( x^0 > 0 \), write it as

\[
\sum_\lambda \int \frac{d^3p}{2E_p(\lambda)} \langle \Omega \mid j^{\mu a}(x) \rangle_{\lambda, p} \langle \lambda, p \mid \mathcal{O}^b(0) \rangle \vert \Omega \rangle. \tag{B14}
\]

In the sum, we can separate the term from the massless particle. Call this particle \( \pi^b \). On Lorentz-invariance grounds,

\[
\langle \Omega \mid j^{\mu a} \pi^b(p) \rangle = f_\pi p^\mu \delta^{ab}. \tag{B15}
\]

Call

\[
\langle \lambda, q \mid \mathcal{O}^a(x) \pi^b(p) \rangle = Z \delta^{a b}, e^{-ip \cdot x} \tag{B16}
\]

Considering the other time ordering, we obtain for the left-hand side a massless scalar propagator, \( i/p^2 \), multiplied by \( Z f_\pi p^\mu \), so the equation is now consistent:

\[
\langle \bar{\Psi} \psi \rangle = \frac{p^2}{p^2} f_\pi Z. \tag{B17}
\]

It is easy to see that in this form, Goldstone’s theorem generalizes to any theory without fundamental scalars in which a global symmetry is spontaneously broken.

Returning to QCD, what about the fact that the quarks are massive? The quark mass terms break explicitly the symmetries. But if these masses are small, we should be able to
think of the potential as “tilted.” This gives rise to a small mass for the pions. We can compute these by studying, again, correlation functions of derivatives of currents. A simpler procedure is to consider the symmetry-breaking terms in the Lagrangian:

\[ \mathcal{L}_{\text{sb}} = \bar{\Psi} M \Psi, \]  

(B18)

where \( M \) is the quark mass matrix,

\[ M = \begin{pmatrix} m_u & 0 \\ 0 & m_d \end{pmatrix}. \]  

(B19)

Since the \( \pi \) mesons are, by assumption, light, we can focus on these. If we have a non-zero pion field, we can think of the fermions as being given by:

\[ \bar{\Psi} = e^{i\pi^a \gamma^5 \frac{\tau^a}{2}} \bar{\Psi}. \]  

(B20)

In other words, the pion fields are like symmetry transformations of the vacuum (and everything else).

Now assume that there is an “effective interaction” for the pions containing kinetic terms \((1/2)(\partial_\mu \pi^a)^2\). Taking the form above for \( \Psi \), the pions get a potential from the fermion mass terms. To work out this potential, one plugs this form for the fermions into the Lagrangian and replaces the fermions by their vacuum expectation value. This gives that

\[ V(\pi) = \langle \bar{q}q \rangle \text{Tr}(e^{i\omega^a \gamma^5 \tau^a} M), \]  

(B21)

one can expand to second order in the pion fields, obtaining:

\[ m_\pi^2 f^2 = (m_u + m_d) \langle \bar{q}q \rangle. \]  

(B22)

**Exercises**

1. Verify Eq. \((\text{B13})\).
2. Derive Eq. \((\text{B22})\), known as the Gell-Mann–Oakes–Renner formula.
Appendix C

Some practice with the path integral in field theory

The path integral is extremely useful, both in field theory and in string theory. This appendix provides a brief review of path integration, and some applications. Many of the examples are drawn from finite-temperature field theory. These are instructive since one can easily write very explicit expressions. They are also useful for understanding the high-temperature universe, and are closely connected to computations which arise in compactified theories.

C.1 Path integral review

Feynman gave an alternative formulation of quantum mechanics, in which one calculates amplitudes by summing over possible trajectories of a system, weighting by $e^{iS/\hbar}$, where $S$ is the classical action of the trajectory. For a particle, the path integral is:

$$Z = \int [dx] e^{iS/\hbar}.$$  \hfill (C1)

Here $\int [dx]$ is an instruction to sum over all possible paths of the particle.

This generalizes immediately to field theory, where surprisingly it is often more useful:

$$Z = \int [d\phi] e^{iS}.$$  \hfill (C2)

For a single field, $\phi$, it is useful to introduce sources, $J(x)$, and to define

$$Z[J] = \int [d\phi] e^{i\int d^4x (\frac{1}{2} (\partial \phi)^2 - V(\phi) + J \phi)}.$$  \hfill (C3)

Green’s functions of $\phi$ can then be obtained by functional differentiation of $Z$ with respect to $J$:

$$T\langle \phi(x_1) \ldots \phi(x_n) \rangle = \frac{\delta}{i\delta J(x_1)} \ldots \frac{\delta}{i\delta J(x_n)} Z[J].$$  \hfill (C4)

For free fields, the integral can be performed by completing the squares. Writing the action as:

$$S_{\text{free}} = \int d^4 x \left( \frac{1}{2} \phi(x) D^{-1} \phi(x) + \phi(x) J(x) \right)$$  \hfill (C5)
with
\[ D^{-1} = \partial^2 - m^2 = p^2 - m^2. \] (C6)

We can complete the squares in the action:
\[ S_{\text{free}} = \int d^4x \left( \frac{1}{2} \phi(x) + \int d^4y J(y)D(y, x) \right) D^{-1} \left( \phi(x) + \int d^4z J(z)D(z, x) \right) \]
\[ - \int d^4x d^4y J(x)D(x, y)J(y). \] (C7)

Now in the free field functional integral, one can shift the \( \phi \) integral, obtaining:
\[ Z_0[J] = \Delta e^{\frac{i}{\Delta} \int d^4 x d^4 y J(x)D(x, y)J(y)}. \] (C8)

Here \( \Delta \) is the free field functional integral at \( J = 0 \). It is the (square root) of the functional determinant of the operator \( D \). \( D \) itself is the propagator of the scalar. This expression can then be used to develop perturbation theory. For example, with a \((\lambda/4!)\phi^4\) interaction, we can write:
\[ Z[J] = \exp \left( i \int d^4x \frac{\lambda}{4!} \left( \frac{\delta}{i \delta J(x)} \right)^4 \right) Z_0[J]. \] (C9)

Working out the terms in the power series reproduces precisely the Feynman diagram expansion.

This has generalizations to non-Abelian gauge theories, with both unbroken and broken symmetries, which we will discuss in the text. We will also find it useful for addressing other questions.

### C.2 Finite-temperature field theory

As an application of path integral methods and because of its importance in cosmology, we consider at some length the problem of field theory at finite temperature.

In statistical mechanics, one is interested in the partition function,
\[ Z[\beta] = \text{Tr} e^{-\beta H}. \] (C10)

For a quantum mechanical system, in contact with a heat bath, this is:
\[ Z[\beta] = \sum_n \langle n | e^{-\beta E_n} | n \rangle, \] (C11)

where \( n \) label the energy eigenstates.

For a harmonic oscillator (unit mass), \( H = \left( p^2/2 + \omega^2/2 \right) x^2 \), and the partition function is:
\[ e^{-\beta F} = \sum_n e^{-\beta \omega (n + \frac{1}{2})} \]
\[ = e^{-\omega\beta/2} \frac{1}{1 - e^{-\beta \omega}}. \] (C12)

Now we can think of
\[ \langle x | e^{-\beta H} | x \rangle \] (C13)
as the amplitude that starting at $x$ one ends up at $x$ after propagating through an imaginary time $-i\beta$. This can be represented as a path integral:

$$\langle x | e^{-\beta H} | x \rangle = \int_{x(0) = x(\beta) = x} [dx] e^{-\int_0^\beta dt L_E},$$

(C14)

where $L_E$ is the Euclidean Lagrangian,

$$L_E = \left( \frac{dx}{dt} \right)^2 + \frac{1}{2} \omega^2 x^2$$

(C15)

(note the signs here!). The partition function is now

$$Z[\beta] = \int_{x(0) = x(\beta) = x_0} [dx] e^{-\int_0^\beta dt L_E},$$

(C16)

i.e. we integrate over the possible values of $x$ at $t = 0$ in order to take the trace. This is the problem of a periodic box in the time direction. For this simple system with one degree of freedom, we can write:

$$x(t) = \sum_n \frac{1}{\sqrt{T}} a_n e^{-\frac{2\pi i n t}{T}}.$$

(C17)

We will simplify the problem slightly by taking $x(t)$ to be complex (you can think of this simply as an isotropic harmonic oscillator in two dimensions). The action of this configuration is:

$$S = \sum_{n=-\infty}^{\infty} \frac{1}{2} (\omega_n^2 + \omega^2) |a_n|^2.$$

(C18)

The path integral is now:

$$Z[\beta] = \prod \int [da_n da_n^* e^{-S_E}].$$

(C19)

The integrals are just Gaussian integrals. For a complex variable, $z$, we have

$$\int d^2z e^{-a|z|^2} = \frac{\pi}{a}$$

(C20)

so we have the result for $Z$:

$$Z[\beta] = \prod \frac{1}{\omega_n^2 + \omega^2}.$$

(C21)

where $\omega_n = (2\pi n)/T$.

Now before trying to evaluate this product, it is useful to pause and note that this can be expressed in terms of the determinant of a matrix. Quite generally, Gaussian path integrals take the form of (inverse) determinants. In this case, if we call $M$ the differential operator:

$$M = \frac{1}{2} \left( -\frac{d^2}{dt^2} + \omega^2 \right)$$

(C22)

its eigenfunctions are just $e^{\omega_n t}$, with eigenvalues $\omega_n^2 + \omega^2$. So $Z$ is just the inverse determinant of $M$. Had we worked with only one real coordinate, we would have obtained the square root of the inverse determinant.
The determinant of an infinite matrix may seem a daunting object, but there are some tricks that permit evaluation in many cases. The first thing is to write the determinant as a sum, by taking a logarithm. In general,
\[ \det M = e^{\text{Tr} \ln(M)} \]  
(C23)
(to see this, diagonalize \( M \)). It is easier to evaluate derivatives of the determinant rather than the determinant itself. We can derive a very useful formula for the derivative of a determinant by writing:
\[ \det(M + \delta M) = e^{\text{Tr} \ln(M + \delta M)} = e^{\text{Tr} \ln(M) + \ln(1 + \text{Tr}^{-1} M \delta M)} \]
\[ = e^{\text{Tr} M} e^{\text{Tr}^{-1} \delta M} \approx \det M (1 + \text{Tr}^{-1} \delta M) \]  
(C24)
Dividing by \( \delta M \) gives the derivative.

In our case, it is convenient to study:
\[ \frac{1}{Z} \frac{d}{d\omega^2} Z = \sum_n \frac{1}{\omega^2 + \omega_n^2}. \]  
(C25)
This is progress. Our infinite product is now an infinite sum. The question is: how do we do the sum? The trick is to look for a periodic function which is well-behaved at infinity, but has poles at the integers. A suitable choice is
\[ \frac{1}{e^{i\beta} - 1}. \]  
(C26)
We can then replace any sum of the form, \( \sum_n f(n) \), by a contour integral,
\[ \frac{1}{2\pi} \int dz f(z) \frac{1}{e^{i\beta} - 1}. \]  
(C27)
Here the contour is a line running just above the real \( z \) axis and back just below. The residues of the (infinite number of) poles just give back the original sum.

Now one can deform the contour, taking one line into the upper half plane, one into the lower, picking up the poles at \( z = \pm i\omega \). This leaves us with:
\[ \frac{dF}{d\omega^2} = \left( \frac{1}{e^{-i\beta} - 1} - \frac{1}{e^{i\beta} - 1} \right) \frac{1}{2\omega}. \]  
(C28)
We could analyze this problem further, but let us jump instead to free field theory. Then
\[ Z[\beta] = \int [d\phi] e^{-\int d^4x \left[ (\partial_\mu \phi)^2 + m^2 \phi^2 \right]} \]  
(C29)
In a finite box, with periodic boundary conditions, we can expand:
\[ \phi(\vec{x}, t) = \sum_{k,m} e^{i\vec{k} \cdot \vec{x} + i\omega_m t} \phi_{k,m} \]  
(C30)
where \( \omega_m = 2\pi m T \).

In this form, we have that
\[ Z[\beta] = \det(-\partial^2 + m^2)^{-1/2}. \]  
(C31)
Again, this is somewhat awkward to work with. It is easier to differentiate:
\[ \frac{1}{Z} \frac{\partial Z}{\partial m^2} = \frac{1}{Z} \int [d\phi] e^{-\int d^4x \mathcal{L}_E} \int d^4z \frac{1}{2} \phi^2(z). \]  
(C32)
This is just the propagator, with periodic boundary conditions in the time direction:
\[
\int d^4z \langle \phi(z)\phi(z) \rangle = \beta V \langle \phi(0)\phi(0) \rangle.
\] (C33)

The propagator is given by:
\[
\langle \phi(0)\phi(0) \rangle = \sum_m \sum_k \frac{1}{\omega_m^2 + k^2 + m^2}.
\] (C34)

We can convert this into a more recognizable form by means of the same trick. The propagator is given by the expression below:
\[
\langle \phi(0)\phi(0) \rangle = \int \frac{d^3k}{(2\pi)^3} \frac{1}{2\pi} \int dz \frac{1}{e^{iz\beta} - 1} \frac{1}{(2\pi nT)^2 + k^2 + m^2}.
\] (C35)

Now deform the contour as before, picking up the poles at \( \pm i\sqrt{k^2 + m^2} \). Both poles make the same contribution, yielding:
\[
\frac{1}{2\sqrt{k^2 + m^2}} \left[ \frac{1}{e^{-\beta\sqrt{k^2+m^2}} - 1} - \frac{1}{e^{\beta\sqrt{k^2+m^2}} - 1} \right] = \frac{1}{2\sqrt{k^2 + m^2}} \left[ 1 + \frac{2}{e^{\beta\sqrt{k^2+m^2}} - 1} \right].
\] (C36)

Note the appearance of the Bose–Einstein factors here. Note also the first term has the structure of the zero temperature expression for the energy; the second is the finite temperature expression. This is what we find differentiating:
\[
\beta F = V \int \frac{d^3k}{(2\pi)^3} \left[ \frac{1}{2} E_k + \beta^{-1} \ln(1 - e^{-\beta E_k}) \right].
\] (C37)

Note the connection with the result for the single oscillator. So far our discussion has been for free field theory, but we can extend it immediately to interacting theories, developing a perturbation order by order in the couplings, just as at zero temperature.

### C.3 QCD at high temperature

Two particularly important cases are QCD and the weak-interaction theory. At low energies, QCD is a complicated theory. But at high temperatures, things drastically simplify. In perturbation theory, if we are studying the free energy, for example, we are instructed to study a Euclidean problem with discrete energies which are multiples of \( T \). So, provided that we do not encounter infrared problems, the free energy should be a power series in \( g^2(T) \), calculable in perturbation theory.

One can argue that there is actually a phase transition between a confined phase and a deconfined phase. To find an order parameter for this transition, we start by considering a Wilson line, running from imaginary time \( \tau = 0 \) to \( \tau = \beta \),
\[
U_T(\vec{x}) = P e^{i \int_0^\beta A^0(\vec{x},\tau)d\tau}.
\] (C38)

Because of the periodic boundary conditions, this is gauge-invariant. The correlation of two such operators is related to the potential of two static quarks:
\[
P(R) = \langle U_T(\vec{R})U_T(0) \rangle = C \exp(-\beta V(R)).
\] (C39)
In a confining phase, with a linear potential between the quarks, \( P(R) \) vanishes exponentially with \( R \). In a Coulomb phase (nearly free quarks), it will tend to a constant. At very high temperatures, we would expect that we could compute \( P \) in a power series in \( g^2(T) \), and that we will find the free quark behavior. Numerical studies show that there is a phase transition at a particular temperature between confined and unconfined phases. The order of the transition depends on the group.

Finite temperature perturbation theory suffers from infrared divergences, even at very high temperature. The problem is the zero-frequency modes in the sum over frequencies. If we simply set all of the frequencies to zero, we have the Feynman diagrams of a three-dimensional field theory. At four loops the divergence is logarithmic. At higher loops, it is power law.

We can understand this directly in the path integral. Consider a massless scalar field. The exponent in the path integral is:

\[
\int_0^\beta dtd^3 x (\partial_\mu \phi)^2. \tag{C40}
\]

For small \( \beta \), assuming it makes sense to treat fields as constant in \( \beta \), the path integral thus becomes

\[
\int [d\phi(\vec{x})] e^{-\beta H}. \tag{C41}
\]

which is the classical partition function for the three-dimensional system.

Thought of in this way, there is a natural guess for how the infrared divergences are cut off. A three-dimensional gauge theory has a dimensionful coupling \( \lambda^2 \). One might expect that such a theory has a mass gap proportional to \( \lambda^2 \) (in three dimensions, the gauge coupling has dimensions of \( \sqrt{M} \)). In the present case the coupling is \( \lambda = g^2 T \). This scale then would cut off the infrared divergence. This suggests that the theory at finite temperature makes sense, but does not help a great deal with computations. The problem is that in four loops, we obtain a contribution \( g^8 \ln(g^2) \), but at higher orders we obtain a power series in \( g^2/g^2 \), i.e. we can at best compute the leading logarithmic term at four loops. It is possible to study some of these issues numerically in lattice gauge theory, which provides some support for this picture.

**Instanton effects at high temperature**

In QCD at zero temperature, we saw that instanton calculations were plagued by infrared divergences. At high temperatures, this is not the case. The scale invariance of the zero-energy theory is lost, and the instanton solution has a definite scale, of order the temperature. As a result, instanton effects behave as \( \exp(-8\pi^2/g^2(T)) \), and are calculable. Thus it is possible to compute the \( \theta \) dependence systematically. This is particularly relevant to the understanding of the axion in the early universe.

**C.4 Weak interactions at high temperature**

The weak interactions exhibit different phenomena at high temperatures. Most strikingly, there is a transition between a phase in which the gauge bosons are massive and one in which they are massless. This transition can be uncovered in perturbation theory. By analogy with the phase transition in the Landau–Ginzburg model of superconductivity, one might expect that the value of \( \langle \Phi \rangle \) will change as the temperature increases. To
determine the value of $\Phi$, one must compute the free energy as a function of $\Phi$. The leading temperature-dependent corrections are obtained by simply noting that the masses of the various fields in the theory (the $W$ and $Z$ bosons and the Higgs field, in particular) depend on $\Phi$. So the contributions of each species to the free energy are $\Phi$-dependent:

$$F(\Phi)V_T(\Phi) = \pm \sum_i \int \frac{d^3 p}{(2\pi)^3} \ln \left( 1 \mp e^{-\beta \sqrt{\vec{p}^2 + m_i^2(\Phi)}} \right), \quad (C42)$$

where $\beta = 1/T$, $T$ is the temperature, the sum is over all particle species (physical helicity states), and the plus sign is for bosons, the minus for fermions. In the Standard Model, for temperature $T \sim 10^2$ GeV, one can treat all the quarks as massless, except for the top quark. The effective potential (C42) then depends on the top quark mass, $m_t$, the vector boson masses, $M_Z$ and $m_W$, and on the Higgs mass, $m_H$. Performing the integral in the equation yields

$$V(\Phi, T) = D(T^2 - T_0^2) \Phi^2 - ET \Phi^3 + \frac{\lambda}{4} \Phi^4 + \cdots. \quad (C43)$$

The parameters $T_0, D$ and $E$ are given in terms of the gauge boson masses and the gauge couplings. For the moment, though, it is useful to note certain features of this expression. $E$ turns out to be a rather small, dimensionless number, of order $10^{-2}$. If we ignore the $\phi^3$ term, we have a second-order transition, at temperature $T_0$, between a phase with $\phi \neq 0$ and a phase with $\phi = 0$. Because the $W$ and $Z$ masses are proportional to $\phi$, this is a transition between a state with massive and massless gauge bosons.

Because of the $\phi^3$ term in the potential, the phase transition is potentially at least weakly first order. A second, distinct, minimum appears at a critical temperature. A first-order transition is not, in general, an adiabatic process. As we lower the temperature to the transition temperature, the transition proceeds by the formation of bubbles; inside the bubble the system is in the true equilibrium state (the state which minimizes the free energy) while outside it tends to the original state. These bubbles form through thermal fluctuations at different points in the system, and grow until they collide, completing the phase transition. The moving bubble walls are regions where the Higgs fields are changing, and all of Sakharov’s conditions are satisfied.

### C.5 Electroweak baryon number violation

We have seen that, at low temperatures, violations of baryon and lepton number are extremely small. This is not the case at high temperature, where baryon number violation is a rapid process, which can come to thermal equilibrium. This has at least two possible implications. First, it is conceivable that these sphaleron processes can themselves be responsible for generating a baryon asymmetry. This is called electroweak baryogenesis. Second, sphaleron processes can process an existing lepton number, producing a net lepton and baryon number. This is the process called leptogenesis. In this section, we summarize the main arguments that the electroweak interactions violate baryon number at high temperature.

Recall that, classically, the ground states are field configurations for which the energy vanishes. The trivial solution of this condition is $\vec{A} = 0$, where $\vec{A}$ is the vector potential. More generally, one can consider $\vec{A}$ which is a “pure gauge,”

$$\vec{A} = \frac{1}{i} \vec{g}^{-1} \vec{\nabla} g,$$  \quad (C44)
Fig. C1. Schematic Yang–Mills vacuum structure. At zero temperature, the instanton transitions between vacua with different Chern–Simons numbers are suppressed. At finite temperature, these transitions can proceed via sphalerons.

where $g$ is a gauge transformation matrix. In an Abelian ($U(1)$) gauge theory, fixing the gauge eliminates all but the trivial solution, $\vec{A} = 0$. This is not the case for non-Abelian gauge theories. There is a class of gauge transformations, labeled by a discrete index $n$, which do not tend to unity as $|\vec{x}| \to \infty$, which must be considered to be distinct states. These have the form:

$$g_n(x) = e^{inf(\vec{x}) \cdot \vec{r}/2},$$

where $f(x) \to 2\pi$ as $\vec{x} \to \infty$, and $f(\vec{x}) \to 0$ as $\vec{x} \to 0$.

So the ground states of the gauge theory are labeled by an integer $n$. Now if we evaluate the integral of the current $K^0$, we obtain a quantity known as the Chern–Simons number:

$$n_{CS} = \frac{1}{16\pi^2} \int d^3x K^0 = \frac{2/3}{16\pi^2} \int d^3x \varepsilon_{ijk} \text{Tr}(g^{-1}\partial_i gg^{-1}\partial_j gg^{-1}\partial_k g).$$

For $g = g_n$, $n_{CS} = n$. The reader can also check that for $g' = g_n(x)h(x)$, where $h$ is a gauge transformation which tends to unity at infinity (a so-called “small gauge transformation”), this quantity is unchanged. The “Chern–Simons number,” $n_{CS}$, is topological in this sense (for $A$’s which are not “pure gauge,” $n_{CS}$ is in no sense quantized).

Schematically, we can thus think of the vacuum structure of a Yang–Mills theory as indicated in Fig. C1. We have, at weak coupling, an infinite set of states, labeled by integers, and separated by barriers from one another. In tunneling processes which change the Chern–Simons number, because of the anomaly, the baryon and lepton numbers will change. The exponential suppression found in the instanton calculation is typical of tunneling processes, and in fact the instanton calculation which leads to the result for the amplitude is nothing but a field-theoretic WKB calculation.

---

1 More precisely, this is true in axial gauge. In the gauge $A_0 = 0$, it is necessary to sum over all time-independent transformations to construct a state which obeys Gauss’s law.
One can determine the height of the barrier separating configurations of different $n_{\text{CS}}$ by looking for the field configuration which corresponds to sitting on top of the barrier. This is a solution of the static equations of motion with finite energy. It is known as a “sphaleron.” When one studies the small fluctuations about this solution, one finds that there is a single negative mode, corresponding to the possibility of rolling down hill into one or the other well. The sphaleron energy is of order

$$E_{\text{sp}} = \frac{c}{g^2} M_w.$$  \hfill (C47)

This can be seen by scaling arguments on the classical equations; determining the coefficient $c$ requires a more detailed analysis. The rate for thermal fluctuations to cross the barrier per unit time per unit volume should be of order the Boltzmann factor for this configuration, multiplied by a suitable prefactor,

$$\Gamma_{\text{sp}} = T^4 e^{-E_w/T}.$$  \hfill (C48)

Note that the rate becomes large as the temperature approaches the $W$ boson mass. The $W$ boson mass itself goes to zero as one approaches the electroweak phase transition. At this point, the computation of the transition rate is a difficult problem – there is no small parameter – but general scaling arguments show that the transition rate is of the form: \footnote{More detailed considerations alter slightly the parametric form of the rate.}

$$\Gamma_{\text{bw}} = \alpha_w^4 T^4.$$  \hfill (C49)

### Suggested reading

The path integral is well treated in most modern field theory textbooks. Peskin and Schroder (1995) provide a concise introduction. High-temperature field theory is developed in a number of textbooks, such as that of Kapusta (1989).

### Exercises

1. Go through the calculation of the free energy of a free scalar field carefully, being careful about factors of 2 and $\pi$.
2. Compute the constants appearing in Eq. (C43). Plot the free energy, and show that the transition is weakly first order.
3. Show, by power counting, that infrared divergences first appear in the free energy of a gauge theory at three loops. To do this, you can look at the zero-frequency terms in the sums over frequency. Show that the divergences become more severe at higher orders.
Appendix D
The beta function in supersymmetric Yang–Mills theory

We have seen that holomorphy is a powerful tool to understand the dynamics of supersymmetric field theories. But one can easily run into puzzles and paradoxes. One source of confusion is the holomorphy of the gauge coupling. At tree level, the gauge coupling arises from a term in the action of the form:

$$\int d^2\theta SW_a^2$$  \hspace{1cm} (D1)

where \( S = -(1/4g^2) + i\alpha \). This action, in perturbation theory, has a symmetry

$$S \rightarrow S + i\alpha.$$  \hspace{1cm} (D2)

This is just an axion shift symmetry. Combined with holomorphy, this greatly restricts the form of the effective action. The only allowed terms are:

$$\mathcal{L}_{\text{eff}} = \int d^2\theta (S + \text{constant}) W_a^2.$$  \hspace{1cm} (D3)

The constant term corresponds to a one-loop correction. But higher-loop corrections are forbidden.

On the other hand, it is well known that there are two-loop corrections to the beta function in supersymmetric Yang–Mills theories (higher-loop corrections have also been computed). Does this represent an inconsistency? This puzzle can be stated – and has been stated – in other ways. For example, the axial anomaly is in a supermultiplet with the conformal anomaly – the anomaly in the trace of the stress tensor. One usually says that the axial anomaly is not renormalized, but the trace anomaly is proportional to the beta function.

The resolution to this puzzle was provided by Shifman and Vainshtein. It is most easily described in a U(1) gauge theory, with some charged superfields, say \( \phi^\pm \). Without masses for these fields, the one-particle irreducible effective action has infrared singularities. In addition, we need to regulate ultraviolet divergences. We can regulate the second type of divergence by introducing Pauli–Villars regulator fields, while the infrared divergence can be regulated by including a mass for \( \phi^\pm \). The \( \phi^\pm \) and regulator mass terms are holomorphic:

$$\int d^2\theta M \Phi_{pv}^+, \Phi_{pv}^-.$$  \hspace{1cm} (D4)
The gauge coupling term in the effective action must be a holomorphic function, now, of $S$ and $M$. But the effective action also includes wave function renormalizations for the various regulator fields:

$$\int d^4 \theta Z^{-1}(\Phi^+\Phi^+ + \Phi^{-1}\Phi^-).$$

(D5)

The wave function factors, $Z$, are not holomorphic functions of the parameters.\(^1\) The physical cutoff is then $Z_p M$, and the physical infrared scale is $Z_p m$. So to determine the coupling constant renormalization in terms of this scale, we need to compute the $Z$s as well. One needs to be a bit careful in this computation. If one works in a non-supersymmetric gauge, such as Wess–Zumino gauge, one needs to actually compute the mass renormalization; the wave function renormalizations will be different for the different component fields.

Starting, then, with our holomorphic expression

$$\frac{8\pi^2}{g^2(m)} = \frac{8\pi^2}{g^2(\Lambda)} + b_0 \ln(m/M).$$

(D6)

we have, in terms of the physical masses:

$$\frac{8\pi^2}{g^2(m)} = \frac{8\pi^2}{g^2(\Lambda)} + b_0(\ln(m/M) - \ln(Z(m)/Z(M))).$$

(D7)

To form the beta function, we need to take

$$\beta(g) = -\frac{g^3}{16\pi^2} \frac{\partial}{\partial \ln(m)} g^{-2}(m) = -\frac{b_0 g^3}{16\pi^2} + \frac{b_0 g^3}{16\pi^2} \gamma$$

(D8)

where

$$\gamma = \frac{d}{d \ln(M)} \ln(Z) = -\frac{4g^2}{16\pi^2}.$$  

(D9)

So there are two- and higher-loop corrections to the beta function. Plugging in, one obtains to two-loop order, for the $U(1)$ theory:

$$-\beta(g) = \frac{g^3}{16\pi^2} + \frac{4g^5}{(16\pi^2)^2}.$$  

(D10)

This is, in fact, the correct result.

This analysis makes clear why the holomorphic analysis is correct but subtle. For non-Abelian theories, it is not quite so straightforward to introduce a holomorphic regulator. One can arrive at the required modification by a variety of arguments. In many ways, the most convincing and straightforward comes from examination of instanton amplitudes. One can also simply make an educated guess by examining the results of two-loop computations. The required relation is:

$$\frac{8\pi^2}{g^2(m)} = \frac{8\pi^2}{g^2(\Lambda)} + b_0(\ln(m/M) - \ln(Z(m)/Z(M))) + C_A \ln(g^2).$$

(D11)

\(^1\)There is much dispute in the literature about whether to write the action with $Z$ or $Z^{-1}$. I have chosen $Z^{-1}$, following the convention of most field theory texts, in which propagators have a factor of $Z$ in the numerator. The reader is free to follow his or her taste.
Differentiating, as before, one obtains the expression for the beta function:

$$\beta(g) = \frac{g^3}{8\pi^2} \frac{3C_A - \sum T_F^i (1 - \gamma^i)}{1 - (C_A g^2 / 8\pi)^2}. \quad (D12)$$

**Exercise**

(1) By examining 't Hooft’s computation of the instanton determinant, argue that the appropriate generalization of the Shifman–Vainshtein formula is that of Eq. (D11). Derive the exact expression for the beta function of Eq. (D12). Verify, by comparison with published results, that this correctly reproduces the two-loop beta function of a supersymmetric gauge theory.
